Wisely, Kernberg leaves open the question of whether such excessive aggressiveness is inborn or associated with particularly malevolent early environments. This means that he is far from being embarrassed by emerging evidence concerning the powerful genetic influences that appear to be present in BPD (Livesley, Jang, & Vernon, 1998; Torgersen, 2000; Torgersen et al., 2000). Borderline individuals fail to achieve the main task of stage 3 of development: to be able to blend the good and bad self and object images into a single representation. Projective identification, pervasive in BPD, is seen as the by-product of the absence of self-object differentiation. The use of massive primitive denial ensures that individuals can ignore their good feelings toward the object and that bad ones dominate their consciousness. There is extreme and repetitive oscillation between contradictory self-concepts—as victim or victimizer, dominant or submissive (Kernberg, Selzer, Koenigsberg, Carr, & Appelbaum, 1989). Transient psychotic episodes can occur because of the ready fusion in self- and object representations, but remain transient because reality testing remains adequate. Self-destructiveness, self-mutilation, and suicidal gestures are claimed to coincide with intense attacks of rage against the object (Kernberg, 1987). They can establish control over the environment by evoking guilt feelings. Kernberg points to the infiltration of the self with aggression as one possible cause, but this is not elaborated. Self-mutilation is also seen as protecting from identity diffusion. Kernberg's treatment approach (transference-focused psychotherapy) is almost the only treatment approach that is well grounded in theory, fully operationalized,

and subjected to careful process as well as outcome investigation (Clarkin, Kernberg, & Yeomans, 1999; Kernberg, Clarkin, & Yeomans, 2002; Kernberg et al., 1989).

Evaluation of the Structural Object Relations Approach

The elegance of Kernberg's theory lies in its bringing together the metapsychological or structural (experience-distant) and phenomenological (what Kernberg called experience-near) levels of description. Splitting describes how individuals with borderline personality organization tend to manage their relationships. Idealization, devaluation, and denial are at once indicators of the organization of intrapsychic relationship representations and tell-tale signs of the individual's failure to generate more advanced mental mechanisms. Thus, the signs of the disorder relate directly to the underlying metapsychological dysfunction. The dramatic separation of good from bad representations is at once the indicator of a pathogenic process (a shift toward primary process thinking), the cause of the process (the failure to integrate internal representations that would lead to the structuralization of an ego), and the content of the process (pathological internalized object relationships). Kernberg goes beyond traditional ego psychology, as the explanation in terms of ego weakness is no longer circular. Ego weakness is coterminous with an active defensive process that leads to the split ego organizations that cannot withstand close contact with bad object representations.

In line with Kernberg's speculations, affect theorists suggest that a constitutional affect bias normally becomes consolidated through repetitions of discrete emotions and comes to be organized into rigid patterns. Psychopathology such as depression arises in association with a sadness bias that may arise as a consequence of constitutional characteristics (e.g., stress reactivity and hypothalamic-pituitary-adrenal axis arousal) and socialization experience (Zahn-Waxler et al., 2000). However, an expanded conception of the structure and organization of emotion may be required, compared to Kernberg's formulations to account for the high levels of comorbidity of emotional disorders (Angold, Costello, & Erkanli, 1999).

Many of Kernberg's hypotheses concerning the ego weakness of patients with BPD are receiving support from work at the Personality Disorders Institute. An example is work on effortful control. This is a temperamental ability to inhibit a dominant response in order to perform a subdominant one and is held to consist of three components: (1) inhibitory control (e.g., "I can easily resist talking out of turn, even when I'm excited and want to express an idea"), (2) activation control (e.g., "I can keep performing

a task even when I would rather not do it"), and (3) attentional control (e.g., "It is very hard for me to focus my attention when I am distressed") (Rothbart, Ahadi, & Evans, 2000; Rothbart, Ahadi, & Hershey, 1994). Clarkin and colleagues (2001) explored the capacity of borderline patients to exert effortful control. Patients with BPD, as would be predicted by Kernberg's theory, are particularly high in negative affect (fear, sadness, discomfort, and frustration) and low in effortful control. The findings suggest that the low capacity for effortful control (i.e., ego weakness) may create the risk for negative affect.

Therapeutic as well as theoretical investigations are underway, including a trial contrasting transference-focused psychotherapy with the best available alternative treatment of BPD, dialectical behavior therapy. Initial findings are encouraging. A pilot study of 17 patients with BPD showed substantial improvements over a year of therapy (Clarkin, 2001). This is the most serious attempt so far to demonstrate the effectiveness of a rigorously described and implemented outpatient treatment program for BPD.

Kernberg's work has been extremely influential worldwide. Perhaps even more important than the high level of theoretical integration he has achieved (systematizing psychoanalytic object relations theory into a unitary framework that is consistent with both classical and structural theory and with the work of British object relations theorists, the main elements being Melanie Klein, Wilfred Bion, Edith Jacobson, and Margaret Mahler) was Kernberg's translation of object relations theory into a realistic clinical method, particularly well described for patients he designated as possessing a borderline personality organization. Other object relations theorists, particularly Kohut and the British theorists (Winnicott, Fairbairn), recommend modifications to technique that bring the analyst as a real person into the foreground in the treatment of patients with borderline personality organization; Kernberg retained the neutrality of classical analysis as well as a focus on being expressive rather than supportive, but he was also more pragmatic than other theorists in the various object relations schools.

Kernberg's commitment to drive theory is laudable and may have been politically important in North American psychoanalysis in the 1970s and 1980s. The Kernberg model might lose little of its power to explain pathology, and gain in coherence, if the concept of drive were abandoned. Aggression does not follow the cyclical nature of biological impulses like sex, thirst, and hunger. It is hard to see what the theory gains through the assumption of a mature biological destructive (and self-destructive) force. The distinction between instinctual acts (early) and drives

(after 3 or 4 years) forces clinicians to look at the hateful, hostile, destructive acts of individuals with BPD as necessarily developmentally early and primitive. As we have noted, assertiveness, gratification from a sense of agency, is characteristic of the infant from the earliest times (3 months; e.g., Watson, 1995), but there is little evidence to support the notion of vengeful, cruel, and annihilating states of mind characterizing early infancy (Stern, 1990, 1995a; Stern, Hofer, Haft, & Dore, 1985).

Kernberg has been committed to research throughout his career. Consequently, his theories and technical recommendations are testable. His etiological hypotheses inevitably share some of the general weaknesses of psychoanalytic formulations, but his contribution remains a landmark, not just because of his advancement of the psychoanalytic developmental framework for personality disorder but also because it brought about a major shift in the epistemic stance taken by psychoanalysts from a clinical hermeneutic to an empirical perspective.

The Interpersonal Relational Approach

The most rapidly evolving psychoanalytic theoretical orientation in the past decade is the so-called interpersonal relational approach. Its hallmark is the rejection of the classical clinical and epistemic frame for psychoanalysis in favor of conceiving of both development and the therapeutic encounter as co-constructed between two active participants, with the subjectivities of both parent and child, analyst and patient generating the shape and substance of the dialogue. There are many important contributors to this young approach, such as Ogden (1994), McLaughlin (1991), Hoffman (1994), Renik (1993), Benjamin (1998), and Bromberg (1998). Like all new psychoanalytic approaches, this one has powerful historical roots. It is a direct descendent of Harry Stack Sullivan's (1953) interpersonal psychiatry school, linked with British object relations approaches by an influential volume coauthored by the most powerful advocate of this new approach (Greenberg & Mitchell, 1983). There are numerous aspects of this shift: Notions of objective truth are supplemented or replaced with subjectivity, intrapsychic with intersubjective, fantasy (poetics) with pragmatics (descriptions of experience); concepts of truth and distortion are supplemented with perspectivism; and a surge for strong theories is replaced by attempts to avoid theoretical bias.

The Developmental Perspective of the Relational Approach

As the theory is not yet fully formalized, we focus on a small number of key ideas to give a flavor of this important

new orientation. Sullivan (1953), like Fairbairn, was dissatisfied with psychoanalysis ignoring the relationship-seeking aspect of human character. He explicitly rejected Freud's model of libidinal development in general and infantile sexuality in particular as an explanation of behavior. Conflict was not seen as being in the individual, but as produced by conflictual, contradictory signals and values in the environment (Sullivan, 1964). In the interpersonalist tradition, psychopathology results when, in the course of development, the satisfaction of interpersonal needs is disrupted by anxiety, the source of which is interpersonal.

Although many of Sullivan's terms are deliberately changed to underscore the separation from traditional psychoanalytic approaches, the elaboration of the constructs reveals fairly close correlations between the interpersonalist and the psychodynamic domains: "security operations" appear to be the same as defense, and "parataxic distortions" appear analogous to internal object relationships. There are genuine differences, however. The therapist's ideal style is not to impart understanding; it is more active and participatory and does not aim to increase insight into unconscious function, but to explore the nature of and reasons for patterns of behavior. The relational model has the interpersonal model as its starting point, particularly the assumption of the interpersonal nature of subjectivity (S. A. Mitchell, 1988). This is not dissimilar to interpersonalist approaches in self-psychology (Stolorow & Atwood, 1991). The relational model includes individuality, subjectivity, and intersubjectivity, with its philosophical basis in Wittgenstein and Davidson, as clearly formulated by Cavell (1994). This is in distinction to traditional self-psychology, where the nuclear self is conceived as intrapsychic. An individual human mind is a contradiction in terms, as subjectivity is invariably rooted in intersubjectivity (Mitchell, 2000). Mitchell conceives of pathology in terms of conflict arising naturally out of the relational nature of development. The basic units of mind are seen as relational configurations that are intrinsically in conflict. This is unlike the traditional object relations theory view of pathology in terms of developmental arrest. The basic concerns of the psychodynamic approach are the matrices of relational bonds within which personal meanings are embedded.

Whereas classical analytic theory stands or falls on its biological foundations (Sulloway, 1979), the heritage of interpersonal relational theories is qualitatively different, more at home with postmodern deconstructive ideas than with brain-behavior integration. A helpful illustration of the primacy of the relational context is Mitchell's understanding of the role of sexuality. Recognized as a powerful

biological and physiological force, it is seen as inevitably emerging in an interpersonal context, which is mutually regulatory, intersubjective, or relational. Its power is not derived from organ pleasure but from its meaning in a relational matrix (Mitchell, 1988). A similar relational argument was advanced by Mitchell (1993) for aggression. The etiological emphasis is on early childhood experience, which teaches the child about “the specific ways in which each of his object relationships will inevitably become painful, disappointing, suffocating, over-sexualised and so on” (Ogden, 1989, pp. 181–182).

There is an emphasis on observable behavior and a reluctance to privilege fantasy over actuality. Reality is not behind the appearance, it is in the appearance (Levenson, 1981). Distortions are produced by interpersonal anxiety in the real world. Fantasy is accepted as formative in the sense that it makes reality relevant (Mitchell, 2000).

The Interpersonal Development Theory of Psychopathology

Mitchell (2000) identified a grouping of four basic modes through which relationality operates to generate psychiatric disorder:

1. Nonreflective, presymbolic behavior is what people actually do with each other that leads to the organization of relational fields around reciprocal influence and mutual regulation. This includes work on the representation of interpersonal interaction into procedural aspects of memory (Crittenden, 1997), whether relegated to this by repression of trauma (Davies & Frawley, 1994) or constraints imposed by cognitive development (Stern, 1994).
2. Affective permeability is the shared experience of intense affect across permeable boundaries where direct resonances emerge in interpersonal dyads (Bromberg, 1998).
3. Experience is organized into self-other configurations, as extensively discussed by Kernberg and other object relations theorists.
4. Intersubjectivity is the mutual recognition of self-reflective agents identified by relationally oriented psychoanalytic feminists such as Chodorow (1989) and Benjamin (1995). The latter explores how any “subject-object discipline” necessarily imposes a dichotomization where only one end of the pole can attain agency. Understanding gender issues in psychological disorder requires a move away from that kind of study. Ultimately, Benjamin argues that fear and defense against a maternal image leads to the ubiquity of masochism in female sexuality.

Relational theory embraces the notion that the absence of a sensitive object causes a child to precociously fulfill a missing parental function, but it is critical of the developmental arrest model (Mitchell, 1988). Childlike needs expressed by adult patients should not be thought of as infantile needs but as adult dependency needs accompanied by intense anxiety. We privilege the earliest periods at the risk of overlooking current relationship needs (Greenberg, 1991). Relational understanding of narcissistic problems represents a compromise between Kohut and Kernberg. The child’s need for the narcissistic illusion of grandiosity is accepted but so is Kernberg’s recognition of the narcissistic illusion as defensive. Mitchell’s suggestion is that the parent must engage in a particular validation through play, a joint pretend that is recognized by both parent and child.

Much of the controversy surrounding the relational approach concerns the declared commitment to a less asymmetrical and more mutual patient-therapist relational structure (Aron, 1996). One focus of this controversy concerns the readiness with which therapists disclose their own feelings (Ehrenberg, 1993). There is a range of views on this, but the mere fact of the controversy signals a willingness to turn away from traditional restrictive conceptions of the social context of offering psychotherapeutic help.

Evaluation of the Interpersonal Relational Approach

The relational approach deviates from most psychotherapeutic approaches in being not primarily developmental in its orientation. The developmental formulations offered lean heavily on other perspectives. As the approach focuses on interpersonal patterns rather than psychiatric categories, evidence for the approach is not readily identified. A review of empirical research in three areas—studies of families and marriages, the role of adult relationships in undoing the adult consequences of destructive childhood experiences, and the relationship of marital variables and the onset and course of depressive disorder—shows that results in all these areas are consistent with the relational assumption that current interpersonal relationships can determine the emergence and course of psychological disturbance. There is substantial developmental evidence that psychopathology is almost inevitably accompanied by relational problems and that good interpersonal relations have a protective influence (e.g., Laub, 1998).

As with all psychosocial approaches, the behavior genetics evidence is a considerable challenge; in the case of interpersonal causes of depression, there are data to support an interaction between life events and genetic vulnerability (e.g., Silberg, Rutter, Neale, & Eaves, 2001). The

techniques of interpersonal therapists differ significantly from their other analytic colleagues in being more active, oriented to current relationships, and avoiding identifying a deeper psychic reality beyond the surface. Interpersonal therapists are supposed to be engaged in collaborative investigation, eliciting information, laboriously sorting out the past from the present, the illusory from the real, continually checking the data.

It is important to note that the strongest evidence for the effectiveness of psychodynamic therapy comes from studies in the strictly interpersonalist tradition. The best controlled studies of relatively brief psychotherapy with mood disorders in adults (E. Frank, Kupfer, Wagner, McEachran, & Cornes, 1991; Shapiro et al., 1995; Shea et al., 1992) and adolescents (Mufson & Fairbanks, 1996) with eating disorders (Fairburn, 1994) and with chronic users of health care services (Guthrie et al., 1999) have all shown interpersonal therapy to be at least as effective as other brief therapies. Most studies that have looked at more classically psychoanalytic therapies have been less focused on particular clinical problems and have had less adequate experimental controls (Roth & Fonagy, 1996). Although the model of development and psychopathology may not compare to more mature psychoanalytic approaches, its potential for generating effective, brief clinical interventions may be as good as or better than other theoretical frameworks.

A PARADIGM SHIFT TO EMPIRICAL SCIENCE: PSYCHOANALYTIC SCHEMA THEORIES

The reification and anthropomorphism of psychoanalytic metapsychological formulations and the inevitable logical contradictions they entail led a number of analysts to evolve theories broadly in line with general systems theory (von Bertalanffy, 1968). Systems theory formulations of development are able to address multiple components of a developmental process at several levels of abstraction simultaneously. In a sense, it affords an updating of Freud's nineteenth-century biological metaphor. A number of implementations have attempted a more or less direct translation of structural psychoanalytic theory into a general systems model (e.g., Basch, 1976; Boesky, 1988; Noy, 1977; Peterfreund, 1971; Rosenblatt & Thickstun, 1977; Tyson & Tyson, 1990). Bowlby's attachment theory is a comprehensive implementation of aspects of psychoanalytic theory using general systems theory. There are several other implementations of British object relations theory and cognitive science research in these terms, including person schema

theory (Horowitz, 1992; Horowitz, Eells, Singer, & Salovey, 1995) and cognitive analytic therapy (Ryle, 1995, 1997). Here we review only one approach, which arguably has been the most influential and is the most closely connected to a developmental frame of reference.

The Interpersonal World of the Human Infant

Daniel Stern's (1985) second book was a milestone for psychoanalytic theories of development. It was normative rather than pathomorphic, prospective rather than retrospective, and focused on the developmental organization of subjective perspectives of the self. Unlike other models, it does not come with an immediate set of clinical applications, but it has been widely used, more or less legitimately, in developmental accounts of personality disorder and neurotic problems. The developmental model delineated by Stern has four phases, each linked to a different sense of self: (1) the emerging self from birth to 2 months; (2) the core self, 2 to 6 months: the emergence of a sense of agency and continuity across time; (3) a sense of subjective self emerging between 9 and 18 months, when intentions may be shared and awareness of emotion in the other arises; and (4) the emergence of language in the narrative self, but, in line with the developmental psychopathology perspective, Stern sees prior selves as conditioning later stages of self-development. Damasio (1999) suggested a model of the development of self and consciousness with important features in common:

1. Damasio's "proto-self" (first-order neural maps) links to the emergent self in that it emerges from subcortical structures in the brain.
2. Second-order neural maps (core consciousness) are generated by higher-order circuits and entail the ways the proto-self is changed by its interaction with the world; it compares the proto-self before and after an interaction in a way that is analogous with Stern's description of the core self (Siegel, 2001).
3. Extended consciousness involving third-order neural maps link to Stern's subjective self, as Damasio describes them, as neural representations of the changes in the core self over time.

Stern (1993) describes the subjective integration of all aspects of lived experience as "emergent moments" that derive from a range of schematic representations (event representations, semantic representations, perceptual schemas, sensorimotor representations) in conjunction with a repre-

sensation of “feeling shapes” (patterns of arousal across time) and “proto-narrative envelopes” that give a proto-plot to an event with an agent, an action, instrumentality, and context (see Bruner, 1990). These are conceptualized in combination as the “schema-of-a-way-of-being-with.” It is distortions in this basic schema that lead to vulnerabilities to psychopathology.

Stern (1993) offers a compelling example of a way-of-being with a depressed mother, describing the baby trying repeatedly to recapture and reanimate her. He describes how depressed mothers, monitoring their own failure to stimulate, may make huge efforts to enliven their infant in an unspontaneous way, to which infants respond with what is probably an equally false enlivened interaction. This model maps very closely onto Sandler’s model of projection and projective identification, and the two need to be combined to achieve a fully coherent account. The child identifies with the representation of the mother’s distorted representation of him, communicated to him by projective identification, and this evolves into an expectation of “a false way-of-being-with” the other.

These schemata come closest to providing a neuropsychologically valid way of depicting a psychoanalytic model of the development of interpersonal experience. Certain features of the model are critical here (see also Stern, 1994, 1995a, 1995b):

1. The schemata are emergent properties of the nervous system.
2. They make use of multiple, simultaneous representations of lived experience.
3. They are based on prototypes and are thus stable in relation to single experiences and naturally aggregate common patterns of lived experience.
4. They can be seen as the simultaneous activation of a set of nodes within a neural network, with each activation automatically strengthening the connections between the nodes (Read, Vanman, & Miller, 1997; Rumelhart & McClelland, 1986).
5. The model allows room for modification from inside as well as outside; reconfiguration is a route by which internally generated activation (fantasy) may strengthen or alter experience.

“Shape” is given to experience through the temporal patterning of arousal. Arousal amalgamates across modalities of experience and, in its purest form, the emotional shape or unfolding across time may be a feature of a prototype experience that is subsequently sought and reen-

acted in interpersonal relationships or in therapy. Arousal systems function by activating the particular modes of cognitive functioning, which, in combination with the experience of arousal, may explain why individuals can persist in repeatedly generating maladaptive interpersonal processes, which nevertheless create desirable configurations or patterns of emotion or cognition.

These moments, or particular ways of experiencing the self with the other, have been exploited by the Boston group in explanations of therapeutic change. It is claimed that change experience in psychotherapy is essentially linked to the rediscovery of these concentrated points of interpersonal experience (Stern et al., 1998). Karlen Lyons-Ruth (1998) points out that classical (problematic) notions of internalization poorly fit the acquisition of procedural knowledge. Both she and Tronick (1998) emphasize the two-person character of such information; awareness of the other is seen as a prerequisite for the articulation, differentiation, and flexible use of these structures. The key assumptions of their model lead the authors inevitably to an interpersonalist psychology. Tronick’s dual consciousness model is probably its clearest expression: “I interact, therefore I am.” As the authors are well aware, they are contributing to a rich tradition, perhaps beginning with Hegel (1807), reinforced by Mead (1934), Cooley (1902/1964), and more recently by Davidson (1987), and in the psychoanalytic sphere by Cavell (1994). Yet, Stern and his colleagues differ from modern psychoanalytic interpersonalists (see Fiscalini, Mann, & Stern, 1995) in offering a coherent psychological model of intersubjectivity, complete with developmental roots and technical implications.

It is likely that general systems theory will be the favored frame of reference for future psychoanalytic developmental models. Stern’s model provides a good fit with developmental data on infancy, but much of its extension to childhood and adult psychopathology is speculative and, on occasion, fanciful. As we have pointed out repeatedly, the adult is not an infant, and continuities from infancy at the level of mental representation are quite unlikely, although they are possible at the procedural implicit level highlighted by Stern and his colleagues. It is in our view more likely that continuity from early childhood will be easier to trace at the level of mental process by identifying those aspects of the psychosocial environment that critically interact with the developmental unfolding of interpersonal mental functions. These interfaces between psychosocial influence and the development of mental structures (mental processes) are most likely to be involved in the psychoana-

lytic understanding of the developmental psychopathological process.

MENTALIZATION AND THE CHANGING AIMS OF PSYCHOANALYSIS

The influence of attachment theory on psychoanalysis has been constant and relatively strong, notwithstanding the adverse reaction that confronted Bowlby's publication of his first major paper on attachment (Fonagy, 2001a). Few psychoanalytic theorists, however, adopt Bowlby's ideas in their entirety. Within modern psychoanalysis, the mentalization based approach is perhaps the only one that fully integrates attachment theory with psychoanalytic constructs (although see Eagle, 1996; Holmes, 2000; Lieberman & Zeanah, 1999; Lyons-Ruth, Bronfman, & Atwood, 1999; Slade, 1999). Simply put, this model assumes that at the highest level, Bowlby's internal working models assume a shared awareness of mental states between self and other. This is sometimes termed by cognitive psychologists "theory of mind" (Baron-Cohen, 1995). The psychoanalytic adaptation of attachment theory assumes that the capacity to envision mental states in self and others develops and is powerfully influenced by the quality of the attachment relationship between the child and primary caregiver.

A Dialectic Model of the Emergence of the Agentive Self

This psychodynamic model, closely linked to attachment theory, focuses on the developmental emergence of the agentive self, particularly as revealed by the vicissitudes of the unfolding of the capacity to mentalize, to conceive of mental states as explanations of behavior in oneself and in others (Fonagy, Gergely, Jurist, & Target, 2002; Fonagy & Target, 1997a). Our approach is rooted in attachment theory but claims a further evolutionary rationale for the human attachment system that goes beyond Bowlby's (1969) phylogenetic and ontogenetic claims for proximity to the protective caregiver in that we consider the major selective advantage conferred by attachment to humans to be the opportunity that proximity to concerned adults affords for the development of social intelligence and meaning making (Fonagy, 2003). The capacity for "interpretation," which Bogdan (1997) defined as "organisms making sense of each other in contexts where this matters biologically" (p. 10), becomes uniquely human when others are engaged "psychologically in sharing experiences, information and affects" (p. 94). The capacity to interpret human behavior requires the "in-

tentional stance": "treating the object whose behavior you want to predict as a rational agent with beliefs and desires" (Dennett, 1987, p. 15). The biologically based capacity for interpretation in psychological terms, which we have labeled the "interpersonal interpretive function," unfolds within the framework of the complex psychological processes afforded by close proximity in infancy to another human being, the attachment figure. Unlike the internal working model, it does not encode representations of experiences; it is not a repository of personal encounters (see Stern's "schemata-of-ways-of-being-with"). It is a mechanism for processing and interpreting new interpersonal experiences.

A number of emotional processing and control mechanisms probably contribute to interpretative function. So far, we have concerned ourselves with the developmental unfolding of four: (1) the labeling and understanding of affect, (2) arousal regulation, (3) effortful control, and (4) the development of mentalizing or mind-reading capacities proper (what we elsewhere operationalize as reflective function; Fonagy & Target, 2002). Close proximity in infancy to another human being may be an important facilitatory condition for the comprehensive development of these capacities. Thus, we claim that the disruption of early affectional bonds not only sets up possibly lifelong maladaptive attachment patterns (e.g., Hamilton, 2000; Waters, Merrick, Treboux, Crowell, & Albersheim, 2000), but also undermines a range of capabilities vital to the processing of information related to mental states. We claim that the link to attachment (the secure base) is made on the basis of the prediction that individuals secure in their early attachment will do better at tasks that call for these capacities.

Our model of agentive self-development may be summarized briefly as follows. The child normally acquires an understanding of five, increasingly complex, levels of self-agency: physical, social, teleological, intentional, and representational (Fonagy et al., 2002; Gergely, 2001a).

1. Children in the first months begin by understanding that they are a *physically agentive entity* with force that is the source of action and that they are agents whose actions can bring about changes in bodies with which they have immediate physical contact (Leslie, 1994).
2. Developing alongside this is children's understanding of themselves as *social agents*. Interactions with the caregiver (from birth) substantiate babies' experience that their behavior produces effects on their caregiver's behavior and emotions. In other words, babies know that they are social agents, that their communicative displays can produce effects at a distance in the social environment (Neisser, 1988).

Both of these early forms of self-awareness probably evolve through the workings of an *innate contingency-detection mechanism* that enables infants to analyze the probability of causal links between their actions and stimulus events (Watson, 1994, 1995). The discovery of the psychological self (mentalization) probably relies on the same mechanism. At about 3 months, there is a change in contingency preference from infants preferring perfect contingency to preferring nearly, but clearly not, perfect contingencies thereafter (Bahrick & Watson, 1985). The initial preoccupation with perfectly response-contingent stimulation (provided by the proprioceptive sensory feedback that the self's actions always generate) allows infants to differentiate their agentive self as a separate entity in the environment and to construct the primary representation of the bodily self. The switch that takes place in the contingency detection module at about 3 months predisposes infants to turn their attention to *high but imperfect contingencies*—the kind of contingent reactivity that is characteristic of the interactions of infant-attuned caregivers, exemplified by their empathic mirroring reactions to the infant's affective displays. Repeated experience with such affect-reflective caregiver reactions is seen as essential for infants to become sensitized to, and to construct differentiated representations of, their internal self-states, a process we term “social biofeedback” (Gergely & Watson, 1996). It is through providing such a state-reflective scaffolding environment that a congenial and secure attachment relationship can vitally contribute to the emergence of early mentalization capacities, allowing infants to discover or find their psychological self in the social world (Gergely, 2001b).

This approach explicitly rejects the classical Cartesian assumption that emotional and other internal mental states are from the start directly experienced introspectively and will, as a consequence, inevitably give rise to the concept of the emotion in the child's mind, just as the perceptual experience of tables may ultimately generate the concept of “table.” In fact, the Cartesian doctrine of the primacy of “first-person” experience has been seriously challenged in current philosophy of mind, cognitive neuroscience, and developmental theory on a number of grounds (Carpendale & Lewis, in press; Damasio, 1994; Dennett, 1991; Gopnik, 1993; Wegner & Wheatley, 1999). In short, we suggest that in the first instance, mental states are discovered through contingent mirroring interactions with the caregiver (Gergely & Watson, 1996, 1999; Target & Fonagy, 1996).

We assume that at first, we are not introspectively aware of our different emotion states. Rather, our representations of these emotions are primarily based on stimuli received from the external world. Babies learn to differentiate the internal patterns of physiological and visceral stimulation

that accompany different emotions through observing their caregiver's facial or vocal mirroring responses to these (Legerstee & Varghese, 2001; Meltzoff, 1990; R. W. Mitchell, 1993; Schneider-Rosen & Cicchetti, 1991). Two conditions need to be met for this to take place: reasonable congruency of mirroring, whereby the caregiver accurately matches the infant's mental state, and “markedness” of the mirroring, whereby the caregiver is able to express an affect while indicating that she is not expressing her own feelings (Gergely & Watson, 1996, 1999). Consequently, two impingements can occur. In the case of incongruent mirroring, the infant's representation of internal state will not correspond to a constitutional self state (nothing real), and a predisposition to a narcissistic (false self) structure might be established. In the case of unmarked mirroring, the caregiver's expression may be seen as externalization of the infant's experience, and a predisposition to experience emotion through other people (a borderline personality structure) might be established (Fonagy et al., 2002). This is an instance of the general principle that the child's capacity to create a coherent image of mind is critically dependent on an experience of being perceived as a mind by the attachment figure. Social understanding is an emergent property of the child's experience of referential interactions with the caregiver about an object, which will inevitably generate the discovery that others have differing beliefs about the world from one's own.

The capacity for attentional control, the ability to inhibit a dominant response to perform a subdominant response, is termed “effortful control by attention” by Posner and Rothbart (2000). Early attachment, which allows the child to internalize the mother's ability to divert the child's attention from something immediate to something else (Fonagy, 2001b), serves to equip children with this capacity. Longitudinal studies of self-regulation demonstrate that the capacity for effortful control is strongly related to a child's observed willingness to comply with maternal wishes (committed compliance), that is, the degree to which he or she apparently willingly embraces the maternal agenda (Kochanska, Coy, & Murray, 2001). Withholding an impulsive response is a prerequisite for mentalizing, as this requires the foregrounding of a distal second-order nonvisible stimulus (mental state) in preference to what immediately impinges on the child (physical reality). The successful performance of theory of mind tasks, for example, must involve the inhibition of the child's prepotent responses to directly perceived aspects of current reality in favor of generating a response on the basis of less salient representations of reality attributed to other minds. Alan Leslie (2000, p. 1245), one of the pioneers in the field, has come

to consider theory of mind “as a mechanism of selective attention. Mental state concepts simply allow the brain to attend selectively to corresponding mental state properties of agents and thus permit learning about these properties.”

Attentional control is also linked to attachment. The major function of attachment is the control of distress, and attentional processes must play a key role if the attachment system is to achieve this objective (Harman, Rothbart, & Posner, 1997). Michael Posner, among others, suggests that the interaction between infant and caregiver is likely to train the infant to control his or her distress through orienting the infant away from the source of distress by soothing and involving him or her in distracting activities. Self-regulation is taught (or, more accurately, modeled) by the caregiver’s regulatory activity. It has been suggested that joint-attention with caregiver serves a self-organizing function in early development (Mundy & Neal, 2001). A study of infants who were disorganized in their attachment found that these infants also had difficulties with social attention coordination in interactions with their caregiver (Schölmerich, Lamb, Leyendecker, & Fracasso, 1997). Cocaine-exposed children with disorganized attachment at 12 months showed the greatest dysfunctions of social attention coordination not only with the caregiver but with an experimenter (e.g., they initiated joint attention less often; Claussen, Mundy, Mallik, & Willoughby, 2002). Evidence from late-adopted Romanian orphans with profound disorganizations of attachment suggests that quite severe attention problems are more common in this group than would be expected both in relation to other forms of disturbance and due to epidemiological considerations (Chugani et al., 2001; Kreppner et al., 2001). From the point of view of our model of personality disorder, we argue that an enfeebled attentional control system is a likely consequence of attachment disorganization, perhaps linked with enfeebled affect representation, and serves to undermine the development of mentalization as well as its appropriate functioning in later development. It is probable that trauma further undermines attention regulation and is associated with chronic failures of inhibitory control (Allen, 2001a; Schore, 2003).

The emergence of mentalizing (what we have also called reflective) function follows a well-researched developmental line that identifies “fixation points”:

1. During the second half of the first year of life, the child begins to construct causal relations that connect actions to their agents on the one hand and to the world on the other. Around this time, infants begin to differentiate actions from their outcomes and to think about actions as means to an end (Tomasello, 1999). This is the beginning of their understanding of themselves as *teleological agents* who can choose the most efficient way to bring about a goal from a range of alternatives (Csibra & Gergely, 1998). The limitation of this stage of experiencing the agentive self is one of physicality. Actors are expected by infants to behave rationally, given physically apparent goal states and the physical constraints of the situation that are already understood by the infant (Csibra et al., 1999; Gergely & Csibra, 2000, 2003). There is no implication here that infants have an idea about the mental state of the object. They are simply judging rational behavior in terms of the physical constraints that prevail and what is obvious in terms of the physical end state that the object has reached.
- We have suggested a connection between the focus on understanding actions in terms of their physical as opposed to mental outcomes (a teleological stance) and the mode of experience of agency that we often see in the self-destructive acts of individuals with BPD (Fonagy, Target, & Gergely, 2000). Thus, slight changes in the physical world can trigger elaborate conclusions concerning states of mind. Patients frequently cannot accept anything other than a modification in the realm of the physical as a true index of the intentions of the other.
2. During the 2nd year, children develop an understanding of agency that is mentalistic: that they and others are *intentional agents* whose actions are caused by prior states of mind such as desires (Wellman & Phillips, 2000) and that their actions can bring about changes in minds as well as bodies (e.g., by pointing; Corkum & Moore, 1995).
2. Around 3 to 4 years of age, understanding of agency in terms of mental causation begins to include the representation of epistemic mind states (beliefs). Young children thus understand themselves as *representational agents*. Their mental states are representational in nature (Wellman, 1990).
4. In the 6th year, we see related advances such as children’s ability to relate memories of their intentional activities and experiences into a coherent causal-temporal organization, leading to the establishment of the *temporally extended self* (Povinelli & Eddy, 1995). It is this autobiographical extension of self to ensure coherence across time that is most rapidly and evidently lost in severe personality disorder, in part, we have argued, because of the impact of trauma on the functioning of autobiographical memory (Fonagy & Target, 1997b). Full experience of agency in social interaction can emerge only when actions of the self and other can be

understood as initiated and guided by assumptions concerning the emotions, desires, and beliefs of both.

A Developmental Model of Severe Personality Disorder Based on the Concept of Mentalization

Unlike other models covered in this chapter, our psychodynamic developmental model is restricted to clinical problems associated with dysfunctions of the agentive self, which we consider to be linked to direct or indirect consequences of dysfunctions of the interpersonal interpretive function. They are normally psychiatrically considered to be severe personality disorder or borderline personality organization (Kernberg, 1967). We suggest that the contingent and congruent responding of the attachment figure in infancy is far more than the provision of reassurance about a protective presence. It is the principal means by which we acquire an understanding of our own internal states, which is an intermediate step in the acquisition of an understanding of others as psychological entities. We have elaborated a complex model of the steps involved and identified a significant body of empirical evidence consistent with it (see Allen, 2001b; Allen & Fonagy, 2002; Bateman & Fonagy, 2004; Bleiberg, 2001; Fonagy, Target, Gergely, Allen, & Bateman, 2003). Here only the highlights of the model are presented.

Incongruent unmarked mirroring associated with a non-secure base generates enfeebled affect representations and attentional control systems. The undermining of these major cognitive mechanisms of attachment results in disorganization of the attachment system. We consider disorganized attachment to be coterminous with a disorganization of the self insofar as incongruent unmarked parenting establishes a part within the self structure that corresponds to the caregiver (as perceived) rather than to the child, but nevertheless exists within the self. We have called this (following Winnicott) the “alien self”: Ideas or feelings are experienced as part of the self that do not seem to belong to the self (Fonagy & Target, 1996). The child, unable to find himself or herself as an intentional being, internalizes a representation of the other into the self with distorted agentive characteristics. This disorganization within the self system accounts for the controlling behavior of 5- to 6-year-old children who had been disorganized in their attachment in infancy (Solomon & George, 1999). Their self-representation is incoherent, and they attempt to create a coherent self-representation through externalizing the alien part of the self by controlling, coercive behavior. Trauma, when combined with the sequelae of a deeply insecure early environment, with enfeebled affect represen-

tation and poor affect control systems as well as a disorganized self structure, has profound effects on the development of such vulnerable individuals:

1. It inhibits playfulness, which is essential for the adequate unfolding of the interpersonal interpretive function (Dunn, Davies, O'Connor, & Sturgess, 2000; Emde, Kubicek, & Oppenheim, 1997).
2. It interferes directly with affect regulation and attentional control systems (Arntz, Appels, & Sieswerda, 2000).
3. Most important, in vulnerable individuals, it can bring about a total failure of mentalization. We consider the last to be a consequence of a defensive adaptive maneuver on the part of the child who protects himself or herself from the frankly malevolent and dangerous states of mind of the abuser by affectively decoupling this capacity to conceive of mental states, at least in attachment contexts (Fonagy, 1991).
4. We believe that adult social functioning is impaired by childhood and adolescent adversity to the extent that adversity causes a breakdown of attachment-related mentalization (Fonagy, Stein, Allen, & Fultz, 2003). There is considerable evidence that maltreated children have specific mentalization deficits and that borderline individuals are poor at mentalization following severe experiences of maltreatment (Fonagy et al., 1996).

There is evidence from the work of Toth and her colleagues that maltreated children have specific deficits in social cognition that point to the flawed functioning of the interpersonal interpretive function (described earlier). In a study of 80 maltreated preschoolers, Macfie et al. (1999) showed clear limitations in the representation of social cognition in a story stem completion task where the story stem called for the relief of distress. In a further study (Macfie, Cicchetti, & Toth, 2001), maltreated children, especially physically or sexually abused children, were shown to manifest more dissociation as measured by a coding system for the MacArthur Story Stem Narratives. Maltreated children showed disruptions of identity and incoherence of parental representations, which may be seen as indicators of a failure of mentalizing or metacognitive capacities (Fonagy, 1997). A more detailed report (Toth, Cicchetti, Macfie, Maughan, & Vanmeenen, 2000) points to an important developmental perspective in that the capacity for social cognition, particularly the complexity of the representation of the parent in conflict-imbued settings, decreased with development, while the children's representation of themselves became increasingly simplified and exaggerated. Perhaps the most compelling evi-

dence for maltreatment-related social cognitive deficit rooted in the child-caregiver relationship is provided by the randomized controlled intervention study reported by Toth, Maughan, Manly, Spagnola, and Cicchetti (2002), in which preschooler-parent psychotherapy was offered to 23 maltreating families. This 12-month intervention aimed at elaborating and modifying the relationship between parents and child by linking current maternal conceptualization of relationships to the mother's childhood caregiving response. Social cognitive measures of outcome favored this group over psychoeducational home visitation or treatment as usual in a range of domains, including degree of maladaptiveness of maternal representation and the quality of self and mother-child relationship representation. In all, recent work from the Mount Hope Family Center (Macfie et al. 1999; Macfie, Cicchetti, & Toth, 2001; Toth et al., 2000, 2002) is consistent with the assumption of profound impairment of social cognition associated with maltreatment and the potential for reducing this impairment through a relationship-focused intervention.

The most serious impact of trauma occurs with the defensive identification of the victim with the abuser. The victim offers the dissociated, alien part of himself or herself as a space to be colonized by the traumatic experience. Through this, the alien self will be experienced as torturing from within, and unbearably painful emotional states will be the consequence. Self-esteem is low (e.g., Mullen, Martin, Anderson, Romans, & Herbison, 1996), as the self is now experienced as evil and hateful, and coercive controlling behavior is used to externalize the alien part of the self and sometimes force the other to attack, not from within but from without. This could explain why many who have been abused who are also borderline in personality structure seek out other relationships where they are victimized (e.g., Russell, 1986). Trauma also affects the arousal system. In Arnsten's (1998; Arnsten, Mathew, Ubriani, Taylor, & Li, 1999; Mayes, 2000) dual arousal systems model, prefrontal and posterior cortical and subcortical capacities are maintained by independent arousal systems. As the level of cortical activation increases through the mutually interactive norepinephrine alpha 2 and dopamine D1 systems, prefrontal cortical function improves. With excessive stimulation, norepinephrine alpha 1 and dopamine D1 inhibitory activity increases, prefrontal activity goes offline, and posterior cortical and subcortical functions (e.g., more automatic functions) take over. It has been suggested that the switch-point between the two arousal systems may be shifted by trauma, undoubtedly accounting for some of the inhibitory effects of trauma on mentalization, at least in contexts of relatively high arousal.

The absence of mentalization reveals developmentally earlier modes of representing subjective experience that have been described in developmental studies (e.g., Gopnik, 1993), but we see them reemerging in severe personality disorder. Three modes are particularly prominent:

1. In the *psychic equivalence mode*, mental reality and outer reality are considered equivalent. There is a mind-world correspondence, where internal is conceived as having the power of external, the experience of mind can be terrifying, and there is an intolerance of alternative perspectives.
2. The *pretend mode* is normally used by the prementalizing child to preserve a world that is unrelated to external reality, where ideas are recognized as not real but also as having no implications for the external world. As revealed by the absence of mentalizing following trauma, it yields emptiness, meaninglessness, and dissociation. Therapy sessions consist of endless inconsequential talk of thoughts and feelings.
3. We have already mentioned the teleological stance as an explanation for why patients cannot accept anything other than a modification in the realm of the physical as a true index of the intentions of the other.

Most critically, as mentalization normally hides discontinuities in the self structure in all of us, when it disappears, discontinuities within the self become more evident to the individual, leading to identity diffusion. Individuals feel attacked from within, and creating the persecutory part of the self externally in the other is felt as the only solution. This is why borderline patients require rather than enjoy relationships: Relationships are necessary to stabilize the self-structure but are also the source of greatest vulnerability because in the absence of the other, when the relationships break down, or if the other shows independence, the alien self returns to wreak havoc (persecute from within) and to destabilize the self structure. We suggest that in the absence of a person who may act as a vehicle to externalize the alien part of the self, persons with BPD achieve self-coherence through the externalization of this part of the self into a part of their body. Attempts at self-harm are acts carried out in a mode of psychic equivalence, when a part of the body is considered isomorphic with the alien part of the self, at the same time as creating a respite from intolerable affects. Attempts at self-mutilation are more common when the patient is in isolation or, critically, following the loss of an other who up to that point could fulfill the task of being a vehicle for the alien part of the self (Herpertz, 1995; Kemperman, Russ, & Shearin, 1997).

Suicide is on a continuum of lethality with other types of deliberate self-harm (e.g., Linehan, 1986) consequent on experience of loss of the other. When patients attempt suicide, we consider their subjective experience is likely to be decoupled from reality (in the pretend mode of subjectivity); in a sense, they believe they will survive (or their true self will survive) the attempt, but their alien self will be destroyed forever. Consistent with our view is evidence that suicide attempters with BPD features perceive their suicidal attempts as less lethal, with a greater likelihood of rescue and with less certainty of death (Stanley, Gameroff, Michalsen, & Mann, 2001). Their sensitivity in social interaction is understandable, as their deep, unbearably painful emotional state is readily triggered and is terrifyingly experienced in the mode of psychic equivalence.

The clinical approach to these patients entails presenting a view of the internal world of the patient that is stable and coherent and can be clearly perceived and may be adopted as the reflective part of the self (Bateman & Fonagy, 2004). A randomized controlled trial on 44 patients treated in a partial hospital setting provides tentative evidence for the clinical value of this approach (Bateman & Fonagy, 1999, 2001, 2003).

CONCLUSIONS AND FUTURE DIRECTIONS

Each psychoanalytic model has produced a perspective on development. The reason for this is simple. The general expectation in the psychoanalytic frame of reference is that the explanation of psychopathology lies in development. Thus, to most psychoanalysts, it is axiomatic that the study of development and the study of pathology concern the same psychic processes. We have seen throughout this review that this assumption is sometimes poorly supported by evidence. Even where infantile modes of thought and the adult mind in distress seem to share characteristics, it is unwise to assume that later development would not have altered both the mechanism and function of early structures to a point where similarities are superficial. In many cases, one cannot help concluding that psychoanalytic theoreticians were developmental reductionists, oversimplifying complex developmental processes and omitting to explore comprehensively how an early deficit could be expected to affect subsequent development. Across a number of theories, the review highlighted how theoreticians tended to assume without evidence that the emergent mode of mental functioning somehow could developmentally date the onset and perhaps even the nature of the pathogenic process. Thus, if the problem of individuals with BPD is one of sep-

aration-individuation, the cause of the problem must be maternal behavior in the rapprochement subphase of separation-individuation. Of course, this is a logical fallacy. In syllogistic reasoning, it is the error of affirming the consequent (post hoc, ergo propter hoc). Sadly, all too often the face validity of such reasoning has carried the day, allowing less rhetorically appealing but more detailed and comprehensive models to be rejected in favor of simpler, but potentially simplistic accounts.

There are many other well-known problems with psychodynamic models of developmental psychopathology. In this review, we intend to tackle some head on; others have to be conceded to. Thus, it is untrue that there is no evidence consistent with psychoanalytic theories, but it is true that most clinicians have not tested their conjectures empirically. The status of clinical data in psychology has shifted over the years. For example, the past 15 years have seen a significant drift toward the use of qualitative, small *n* research, albeit with a deeply phenomenological epistemological standpoint. This is not to say that current psychoanalytic clinical research meets the criteria of this research approach. But it is easier to imagine that with some effort, these new methodologies could be adapted to exploring psychoanalytic developmental constructs.

There have been appropriate criticisms of the absence of specificity in psychoanalytic theoretical speculations. Concepts such as narcissism, borderline personality, and even psychosis are used without care in definition, and consequently related phenomena are poorly understood, for example, the predominance of boys presenting with psychiatric problems in middle childhood. Psychoanalysts frequently show an apparently staggering lack of awareness of the potential impact of broader cultural influences. By the same token, analysts often appear not to recognize the way they may be influenced by their own cultural context. Striking examples of this are the issue of gender in psychoanalysis that was probably only appropriately addressed in the 1970s and 1980s, and the issue of sexual orientation, which is only currently being taken on board by the psychoanalytic community. By contrast, race and racism have never been seriously tackled by psychoanalysts, even though unconscious prejudice on the face of it appears to be a highly appropriate topic for psychoanalytic scrutiny.

It is hardly an intellectual challenge to list epistemological and social concerns about psychoanalysis. It is much harder to justify why serious intellectual energy should still be committed to this area when a strong case could be made that anything of scientific value that had ever existed in the discipline must have surely already been exploited and integrated into current streams of inquiry. Indeed, in

some respects, the very success of the psychodynamic approach has undoubtedly contributed to its current crisis. Many of the major insights that psychoanalysis had to offer were taken on board by other orientations, such as cognitive-behavior therapy and folk psychology.

So why should psychoanalytic ideas continue to be taken seriously? First, because psychoanalysis studies human subjectivity at its most complex. It therefore provides an essential counterweight to advances in neuroscience and molecular genetics, which would otherwise potentially obliterate or oversimplify the study of mental disorder. As we hunt for the biological basis of anxiety and depression and the impact of childhood maltreatment, it behooves us to retain our sophistication concerning the nature of the impact of human experience as we attempt to identify its biological corollaries. The interaction between genes and environment can be found only if we retain our grasp of the full complexity of how the human mind grapples with the challenges of adaptation. In this context, it is essential that we do not neglect the nonconscious domain of human experience. Given that folk psychology was able to substantially ignore this facet of human function for most of its existence, we should be wary that our concern with unconscious processes and, most important, unconscious motivation in human behavior does not once again go underground.

Two further points are worthy of mention. First, psychoanalysis has been traditionally concerned with early experience, and modern neuroscience has by and large affirmed the pertinence of the study of this early period. Second, cognitive psychology and cognitive-behavior therapy have increasingly converged with psychoanalytic interest in studying the influence of relationship representation patterns on human conduct. Schema theory, systemic approaches, interpersonal approaches, and attachment theory have converged on this problem since the mid-1980s. It would be a shame if the considerable accumulated experience of 100 years of study of this domain were to be lost through disinterest and neglect.

Psychoanalysis has survived 100 years and continues to produce new ideas and recruit advocates. Some of the greatest minds ever to become interested in psychology and the mental disorders explored or adopted the frame of reference of psychoanalysis. They probably did so because it offered the richest set of ideas as elements for describing mental functioning. What are the strengths of the approach that permit this? The following may be an inadequate attempt to answer the query about the resilience of the psychodynamic approach, which a historian of science 100 years from now might raise:

1. **Generativity:** Many important psychological theories of psychopathology acknowledge that psychoanalytic ideas have inspired their lines of research (e.g., learned helplessness theory, schema theory, attachment theory, aggression and hostility as causes of psychosomatic conditions, self-serving cognitive distortions based on defense mechanisms).
2. **Unifying explanations:** Diverse symptoms and behavior can reflect a single hidden problem. For example, why are narcissistic individuals often forgetful of names, prejudiced, inconsiderate of others' time, vulnerable to slights, and unable to remain in love? Psychoanalytic accounts, whether self psychological or based on other object relations views, offer single explanations for such groups of phenomena.
3. **A dynamic approach—development as a series of compromise formations:** This gives depth, texture, and complexity in line with new knowledge emerging from both neuroscience and developmental psychopathology. Many psychoanalytic accounts provide satisfying functionalist explanations of observed patterns of behavior and the observed characteristics of mental representation.
4. **The mind as an instrument:** Theory is built from the sensitivity of the therapist in generating models for understanding thoughts, feelings, and behavior beyond the normal range of conscious experience and commonsense psychology. Psychoanalytic listening, regardless of specific model, perhaps equips clinicians to handle and make sense of particularly intense and disturbing interactions. The resulting understanding is more complex and psychologically deeper than other, omnibus theories of human behavior (cognitive-behavioral, humanistic, systemic), even if psychoanalysis is therapeutically no more effective. This contains the appeal of psychoanalytic ideas for many clinicians and others.

The Role of the Internal World in the Expression of the Human Genotype

All agree that development involves a gene-environment interaction. In the case of honeybees, the reproductive and social roles of colony members are fixed by events that occur during the first few days of larval development. Worker or queen bee status is not apparently encoded in the genotype but follows from the differential treatment of larvae by worker bees, resulting in differential gene expression, both up-regulation and down-regulation (Evans & Wheeler, 2000). Some quantitative human behavior genetic studies also strongly suggest interactive processes

whereby environmental exposure triggers genetic vulnerability. For example, the classic Finnish adoptive family study of Schizophrenia suggests that children with a schizophrenic biological parent are more likely to develop a range of psychiatric problems if, and only if, they are adopted into dysfunctional families (Tienari, Wynne, Moring, Lahti, & Naarala, 1994). Bohman (1996) reported that criminality appeared to be associated with a genetic risk only if children whose biological parents were criminals were adopted into dysfunctional homes. More recently, studies of single gene-environment interactions are being reported. To give just one example, the promoter region of the serotonin transporter gene (SLC6A4) is involved in reuptake of serotonin at brain synapses; in the gene-linked polymorphic region, the short (S) allele has a lower transcription efficiency than the long (L) allele. There is inconclusive evidence on direct association with depression (Lerch, 2004). However, an analysis of the Dunedin longitudinal sample has dramatically demonstrated that in the presence of three or more traumatic life events, the likelihood of a diagnosis of Major Depression for those with the S allele increases from 10% to 28% to 32%, whereas in those with the L genotype, the risk of an episode of Major Depression is 10% to 16% regardless of life events (Caspi et al., 2003). Genetic risk may or may not become manifest depending on the quality of the family environment to which a child is exposed. But if this is such a pervasive process, why is the quantitative behavior genetic evidence for gene environment interaction so sparse? Plomin and McGuffin's (2003) systematic review failed to find more than a handful of examples.

We think one aspect of the answer to this complex question is obvious: They failed to find more examples because behavior genetics of developmental psychopathology often studies the *wrong* environment. The environment that triggers the expression of a human gene is not the observable, objective environment. The child's experience of the environment is what counts. The manner in which environment is experienced will act as a filter in the expression of genotype into phenotype. And here we touch on the pivotal role of psychoanalysis for genetic research. The primary concern of psychoanalysis is with the interaction of multiple layers of representations in generating developmental outcomes. Data from genetics call for exactly such sophistication in understanding the way genes may or may not be expressed in particular individuals.

The pathway from genes to phenotypes is a tortuous one, along which genetics and environment constantly interact (Elman et al., 1996). Internal and external stimuli, steps in

the development of the brain, hormones, stress, learning, and social interaction alter the binding of transcription regulators (Kandel, 1998). There is substantial individual variability in response to the risk factors of stress and adversity. Much of this variability is poorly understood (Rutter, 1999, 2005), but it underscores the potential importance of intrapsychic variables. Whether or not specific environmental factors trigger the expression of a gene may depend not only on the nature of those factors, but also on the way the infant or child experiences them, which will be an intrapsychic function, determined by conscious or unconscious meaning attribution to these experiences. The quality of this experiential filter may in turn be a function of either genetic or environmental influences, or their interaction (Kandel, 1998). Thus, intrapsychic representational processes are not just consequences of environmental and genetic effects—they may be critical moderators. An intrapsychic perspective may be helpful in considering, not just what precipitates personality and its disorders, but also which processes influence the course of disorders for better or worse. Five years ago this was theory; now, the collaboration of molecular geneticists and developmental research is making it a reality.

We suggest that psychoanalysis needs to look to the cognitive neurosciences to find its intellectual fulfillment. Current theorization in neuroscience has in the past been sadly devoid of considerations of emotional life and relationality, even around topics such as social development, where the subject matter directly concerns the child's subjectivity. The evidence clearly shows that it is naïve to assume that the child's genotypic destiny is fulfilled in a hermetically sealed brain, somehow isolated from the social environment within which ontogeny occurs and the sound adaptation to which is the organizing purpose of the whole system. Subjectivity, the understanding of the individual response, will be an essential piece in putting together the microbiological puzzle of genetic expression.

Psychoanalysis, with its focus on the representation of subjectivity and how this emerges from early development, might have much to contribute to the understanding of how individual differences in the quality of functioning of basic mental mechanisms arise. Here we suggest that infant attachment functions, in part at least, to facilitate the development of an interpersonal interpretative capacity. We propose that a major selective advantage conferred on humans by early intimate and intense relationships with the primary caregiver was the opportunity it afforded for the development of social intelligence and meaning making. The capacity for "interpretation," which Bogdan (1997) de-

defined as “organisms making sense of each other in contexts where this matters biologically” (p. 10), becomes uniquely human when others are engaged “psychologically in sharing experiences, information and affects” (p. 94). The quality of the early relationship plays a major role in determining the robustness of that capacity, but the nature of such relationships is less relevant to later relationship patterns (Fonagy, 2003). But the interpretive capacity in turn has a key role in the processing of social experience. The level of interpersonal interpretative functioning will be reflected in an individual’s ability to function in close interpersonal relationships without needing to have recourse to strategies for amplifying the distinction between self and other representations. The unfolding of disturbance over time is conditioned by the interpretive capacity. We speculate that the expression of pathogenic genotypes is made more likely by the poor functioning of a mechanism designed to differentiate the psychological state of self and other.

This is a function of immense importance, as the laborious move from genotype to phenotype is conditioned this way. A full understanding of the interaction between individual mentalized representations of life experience and the expression of genetic dispositions is the task of psychoanalytic psychopathology of the next decades. Kandel (1999, p. 508) cites Francois Jacob (1998) who wrote in *Of Flies, Mice and Men*, “The century that is ending has been preoccupied with nucleic acids and proteins. The next one will concentrate on memory and desire. Will it be able to answer the questions they pose?”

Neuroscience and Future Clinical Applications of Psychoanalytic Ideas

And what of clinical applications of psychoanalysis? The outcome of psychoanalytic therapy has not been the focus of this chapter. Accumulating evidence is moderately favorable to psychodynamic approaches (Fonagy et al., 2001; Fonagy, Roth, & Higgitt, in press; Leichsenring, Rabung, & Leibling, 2004), as it is to most theory-based structured interventions (Roth & Fonagy, 2005). If psychoanalytic therapy is to continue to be able to make a contribution in the future, it will have to be even more firmly rooted in developmental psychopathology. As we increasingly appreciate that psychiatric disorders of adulthood are rooted in abnormalities already observable in childhood or adolescence, there will be a merging of (developmental) psychopathology and psychotherapy research. It is likely that the elucidation of pathogenic mechanisms—essential for the development of effective and specific psychological interventions (Kazdin, 2003)—will be achieved only through developmental observations. The structured, manualized

psychodynamic psychotherapy techniques of the future will need to be designed to specifically address empirically established developmental dysfunctions. Future psychotherapy trials will be increasingly seen as the only viable experimental tests of rival psychosocial etiological models of personality (e.g., Hudson, Kendall, Coles, Robin, & Webb, 2002; Toth et al., 2002).

One reason for the thin evidence base of psychoanalytic psychotherapy is the non-symptom-oriented nature of the psychodynamic approach to therapy (Gabbard, Gunderson, & Fonagy, 2002). The measures of outcome used in many trials leave room for improvement from a psychodynamic standpoint. Most self-report measures in standard use are oriented toward symptom distress and are of greatest relevance to trials of pharmacological products designed to address specific psychiatric symptoms; they are far more likely to change naturally without intervention than measures of functioning (e.g., Grilo et al., 2004). The virtual absence of user involvement in the devising of these measures has been a flaw in this approach and one that might have selectively disadvantaged long-term psychodynamic therapy, which is often favored by those receiving that kind of help (Seligman, 1995). Most outcome measures are prone to bias and are potentially highly reactive with the mode of intervention (Sechrest, McKnight, & McKnight, 1996). Nonbiased, nonsubjective measures of outcome might provide firmer grounding for evaluating psychoanalytic therapies on a level playing field with cognitive-behavioral approaches, which often are better suited to symptom-focused outcomes measurement. Neuroscience (particularly brain imaging) might deliver nonsubjective measures of outcome sooner rather than later. Psychoneurobiology research is identifying neural correlates of complex subjective states (Adolphs, 2003), for example, the experience of social exclusion (Eisenberger, Lieberman, & Williams, 2003) and concern about the mental states of another person (Frith & Frith, 2003). There are indications that scanning techniques that allow the simultaneous imaging of two individuals interacting (King-Casas et al., in press) will be able to offer unbiased indicators of relationship quality as this changes as a consequence of psychological therapy. When the neurobiology of social cognition is clearer and more accessible, unbiased outcomes of psychotherapy based on brain-behavior interaction might cast psychodynamic interventions in a more favorable light as well as clarifying and assisting with the specification of currently overly complex psychoanalytic ideas.

The greatest contribution of neuroscience to psychodynamic psychotherapy is likely to be through progress in

molecular biology. As molecular genetic findings unfold over the next few years, it is likely that biological vulnerability will become increasingly detectable; although single genes and polymorphisms will probably never account for a large proportion of variability, combinations of genes may increasingly identify specific types of environmental vulnerability (Plomin & McGuffin, 2003). Discoveries such as those of Caspi and colleagues (2003) concerning vulnerability for life-event-triggered depression among those with the short allele of the serotonin transported gene, described earlier, may create important opportunities for targeting psychodynamic interventions at those with the S genotype. It is not yet clear what aspects of life events might represent a depressogenic effect to those with the S allele. It might well be that enhancing the capacity of those with the S genotype to cope with adverse life events would reduce the potency of the underlying biological vulnerability to trigger Major Depression. The field of mental illness prevention, although impeccable in its logic, has always had difficulty in appropriately targeting preventive interventions when demographic data were the sole guide to identifying the indicated group. The rationale for enrolling a large number of individuals into prevention programs who are unlikely ever to develop the problem has often led to selective uptakes and prevented a genuine test of the prevention approach (Beardslee, Gladstone, Wright, & Cooper, 2003). Preventive efforts will be enhanced by having powerful biological indicators of environmental vulnerability, so that individuals can appreciate that reducing the impact of specific types of environments will protect them from the disease process.

The true importance of molecular biology in this context, however, is in opening a vista of biologically indicated psychosocial treatments—not just preventions. As we begin to understand the causal path that disease processes follow in the vulnerable brain, the need for specific psychosocial treatments to assist individuals with these vulnerabilities will become acute. Knowing that, in individuals with the S/S genotype, severe maltreatment doubles the probability of Major Depressive Disorder (to over 60% from 30% for those with the genotype) helps us to focus interventions on childhood maltreatment for the first group to a greater extent than for the L/L group. It would be fascinating to know whether severely maltreated individuals with these genotypes give different weights to this experience with respect to their disorder. The psychotherapy would be designed to help these individuals to circumvent and, if possible, reverse the impact of this type of psychosocial event on brain function.

Future psychoanalytic developmental, clinical, and treatment research must entail the removal of the opposition between psychosocial and biological perspectives. As we identify specific brain dysfunctions associated with psychological disorders, the need for psychotherapy will become greater—not less, as some fear and others advocate. Pharmacological interventions specific to the underlying cause of brain dysfunction, particularly etiology-associated brain dysfunctions, will be a long time coming. So far, there is little evidence that genotyping can indicate the choice of psychotropic medication (e.g., Solvason, Ernst, & Roth, 2003). Psychological approaches, in contrast, can be developed and tested rapidly. Psychotherapy can be available to provide a work-around, a set of techniques that the mind can use to overcome a biological deficit. This is not to suggest that psychotherapy could be to the brain as physiotherapy is to the healing of the musculoskeletal system (although this would be nice if true), but rather that the human mind as a system evolved to be able to bypass and overcome dysfunctions in the physical organ on which it depends: the brain. It was to exploit this self-healing capacity that Freud invented psychoanalytic psychotherapy. Increased neuroscientific knowledge will help us to help the brains of our patients to devise and make use of sometimes complex and sometimes simple mental strategies to cope with weaknesses in their brain function, whether these are caused by genetic vulnerability, developmental assault, or a unique combination of the two.

The future of psychoanalysis, if it is to have a future, is in the context of an empirical psychology, abetted by imaging techniques, neuro-anatomical methods, and human genetics. Embedded in the sciences of human cognition, the ideas of psychoanalysis can be tested, and it is here that these ideas can have their greatest impact. (Kandel, 1998, p. 468)

SUMMARY AND FUTURE DIRECTIONS	787
REFERENCES	788

The application of cognitive-developmental paradigms in the study of psychopathology originates from a broader attempt to integrate principles of developmental psychology with those of clinical psychology and psychiatry. One consequence of these efforts has been the emergence of developmental psychopathology as a field of inquiry (Achenbach, 1982; Cicchetti, 1984; Garmezy & Rutter, 1983; Kazdin, 1989; Noam, 1984; Rutter, 1988; Wenar, 1982). The utilization of a cognitive developmental approach in the study of developmental psychopathology was initially alluded to by Rosen (1977) as “cognitive developmental psychopathology.” Achenbach (1990) later situated this approach in the context of developmental psychopathology.

Both researchers and clinicians have begun to use this cognitive approach as a basis for exploring and understanding maladaptive behavior (Gordon & Arbuthnot, 1987; Salter, Richardson, & Martin, 1985; Swett, 1985) and psychopathology (e.g., Gondolf, 1987; Hoar, 1983; Ratcliff, 1985; Reinhard, 1990; Strauss & Ryan, 1988; Wilbur, Rounsaville, Sugarman, Casey, & Kleber, 1982), and for use of innovative methods of clinical intervention (Abroms, 1978; Sperry, 1975; Swensen, 1980; Young-Eisendrath, 1982).

Since the cognitive-developmental “revolution” in psychology, a riddle has intrigued many developmental scholars and practitioners. This riddle concerns the nature of the relationship between cognitive complexity and adaptation: Are more complex levels of cognition, social cognition, or personality development also characterized by more successful adjustment patterns? In most developmental traditions, more complex development is also viewed as more adaptive (e.g., Piaget, 1965, 1977, 1978). The stepwise progression from immature thought and impulsivity to complex, self-reflective, and tolerant forms of maturity consists of many components of mental health, yet many people at mature levels of development struggle with mental illness, neurosis, and dysfunctional adaptation to life. How is that possible?

The goal of this review is to assemble the large body of empirical evidence, to shed some light on the nature of this problem, and to add a level of synthesis to this line of developmental psychopathology research. Further questions include: Are there patterns of association between different developmental levels and typical psychological symptoms and psychiatric diagnoses? How has this field of inquiry evolved from simple correlational studies to complex multivariate models?

In this chapter, we review both published and unpublished reports using Loevinger’s Washington University Sentence Completion Test in terms of clinical research, assessment, and potential treatment implications. We derive our cognitive developmental approach to developmental

psychopathology from a definition of the field set forth by Sroufe and Rutter (1984) as “the study of the origins and course of individual patterns of behavioral maladaptation.”

In Loevinger’s theory, ego is a cognitive construct, a frame of meaning combining views, approaches, and ideas about one’s self—what Loevinger calls “self-theory” (Hauser, 1993; Loevinger, 1976)—and the world around that self. Had Loevinger introduced it later, she would have labeled her work as relating to the development of self; at the time, the word ego seemed to depict the range of processes in which she was interested (Jane Loevinger, personal communication, 1996).

However, today, the term ego sometimes creates confusion as investigators are reminded of the psychoanalytic ego, which is not what Loevinger means (see also Vaillant, 1993). Ego is a frame of reference that enables a person to create new meanings and interpret events and emotions based on personal experience. It includes content (views, memories, isolated ideas) and structure (the complexity of the relationships between those ideas). As pointed out by a number of scholars, this amalgam of content and structure makes Loevinger’s theory quasi-structural rather than purely structural in the way Piaget and the cognitive psychologists in his tradition thought of structure (Loevinger, 1991, 1993; Manners & Durkin, 2001; Noam, 1993). Quasi-structural refers to the fact that ego development consists of a mixture of cognitive complexity and content of thought and feeling. Whereas structural psychologists try to differentiate structure and content, Loevinger combines them, having found that people at different developmental levels have typical preoccupations and expected contents of thought that should not be “screened out” but made part of the definition and measurement of what constitutes a level of ego development.

It follows logically from the quasi-structural nature of the ego and its complexity as a “master trait” that no single dimension will be enough to describe the ego in its entirety. Loevinger distinguished four dimensions of the ego: impulse control, cognitive complexity, interpersonal relations, and conscious preoccupations. These dimensions can vary. There are good arguments to be made that all of these dimensions are separate domains of the self and have their own developmental line (e.g., Holt, 1998; Loevinger, 1986; Noam, 1993); there is also good evidence that people attempt to structure the world in some cohesive way that cuts across domains. It is important both to study a person from the perspective of domain specificity and to explore the discrepancy of different domains. The simultaneous importance of looking at the overarching self and its developmental path makes ego development theory and measurement very attractive.

EGO DEVELOPMENT

According to Loevinger, ego develops along a sequence of developmental stages, from the Impulsive stage, where the world is perceived in its dichotomy of black and white (good and bad) and the person is enveloped in his or her own egocentrism; to Self-Protective, where the world is perceived as hostile and threatening; to Conformist, where ideas and behaviors are governed by external rules; to Self-Aware, where self, at last, becomes the focus of its own awareness; to Conscientious, where one's conscience becomes its own judge; to Individualistic, where the value of an individual is fully appreciated; to Autonomous, where the life and the self are perceived in their complexity and interrelatedness. The fuller descriptions of each stage and its characteristics can be found elsewhere (e.g., Hauser, 1976; Loevinger, 1976, 1993; Loevinger & Hy, 1996; Manners & Durkin, 2001; Noam, 1998).

In Loevinger's original theory, only five stages were distinguished (Impulsive, Self-Protective, Conformist, Conscientious, and Integrated); the number was then expanded to seven by making the transitional substages (Conformist/Conscientious and Conscientious/Integrated) separate stages (Loevinger & Hy, 1996), to which Cook-Greuter (2000) added two more: Construct-Aware (E9) and Transcendent (E10). Thus, the most current version of the theory acknowledges the existence of the nine consecutive stages: from E2 (Impulsive) to E10 (Transcendent). The information about stages, summarized in Table 19.1, is based on the descriptions from the latest texts: the Loevinger and Hy manual and Cook-Greuter's paper.

THEORETICAL MODELS OF LINKAGE BETWEEN EGO DEVELOPMENT, PSYCHOPATHOLOGY, AND MENTAL HEALTH

It has become a widely accepted trend in psychology and psychiatry that mental health and psychopathology should be understood, at least in part, in developmental terms (e.g., Cicchetti, 1984, 1990; Noam, 1988), in other words, that developmental dimensions can lend themselves as important lenses for developmental psychopathology.

It is not surprising that a steady number of studies have been conducted using the Loevinger model. We now have sufficient evidence to warrant an in-depth review and to critically reflect on the central dimension of the relationship between ego development and psychopathology.

There are four theoretical perspectives on the nature of the ego development-mental health relationship. On one ex-

treme is the notion that development and mental health are, in fact, one and the same: Individuals at lower stages of development are less "mentally healthy," and those at more mature stages enjoy greater mental health. This is especially the case when people remain in ego development positions beyond their normative age ("age-stage dysynchrony").

Among the evidence in support of this claim is the fact that the stepwise progression from immature thought and impulsivity to complex, self-reflective, and tolerant forms of maturity consists of many components of mental health. Accepting the contradictory nature of the self, relationships, and the world at large is a hallmark of complex development and represents positive adaptation, which clinicians also tend to refer to as mental health. Thus, social-cognitive development from Piaget to Kohlberg and to Loevinger refers not only to evolving structures of meaning, but also to better adaptations between the person and the world. Higher stages promote more stable adaptations to the social world and also indicate more secure mental health. A person who is developmentally immature, for example, has fewer tools at his or her disposal to interpret the actions of others. As a consequence, he or she is more likely to interpret statements of others as hostile and rejecting. This lack of understanding of the inner workings of another person and the multifaceted nature of human communication is a cognitive and developmental vulnerability. As a consequence, the likelihood of distorting ambiguous information and reacting in an aggressive and retaliatory manner is great.

The second view of the association between mental health and development is that the two are conceptually and empirically distinct phenomena. Anyone can be afflicted with any form of psychopathology at any developmental position. The mechanisms underlying psychopathology and ego development are truly orthogonal. The fact that many people at mature levels of development struggle with mental illness, neurosis, and dysfunctional adaptations to life is strong evidence in support of this view. This is also Loevinger's position. She implied in a 1968 chapter entitled "The Relation of Adjustment to Ego Development" that the evolution of the ego and mental health are orthogonal: two distinct constructs that have no conceptual overlap.

A less extreme position than the first two consists of a strong positive relationship between development and mental health such that people at higher stages of development are better adapted or better able to adapt and, therefore, are more apt to be mentally healthy. To put it another way, mental health supports the maturation of the ego. This model is quite common in developmental research; a positive association between development and mental health has been stated or implied by researchers in cognitive development

TABLE 19.1 Ego Development Stages and Features

Level	Code	Features
Impulsive	E2	Impulsivity; dependence on others; world understood in terms of simple dichotomies: good and bad, black and white; prevalence of physical needs
Self-protective	E3	Hostility, seeing interpersonal relationships as exploitative, opportunistic behavior
Conformist	E4	Identification with the group and its authority; preoccupation with appearance, material things, social acceptance, and belonging; stereotypic perception of people
Self-aware	E5	Acute sense of distinction between the self and the group; attention to inner states
Conscientious	E6	Reflectivity; importance of self-evaluated standards; high value of achievement; excessive responsibility for others
Individualistic	E7	A sense of individuality; greater tolerance for individual differences; concern for problems of dependence and independence
Autonomous	E8	Search for self-fulfillment; recognition of other people's need for autonomy; high tolerance of ambiguity and recognition of paradoxes
Construct-aware	E9	Seeing the global world beyond one's culture; rationality; inner conflict around existential paradoxes; fear of losing self
Transcendent	E10	Acceptance and understanding of time-space continuum, of unity concepts; being, noncontrolled conscience, tolerance, full empathy

(Piaget), moral development (Kohlberg), and interpersonal development (Selman) and is one that Loevinger would also subscribe to as an empirical fact. However, this view implies that although people at more mature developmental levels are not necessarily shielded from psychopathology or dysfunctional adaptations, there is greater probability of mental health.

What makes this general view on the relationship between development and mental health more complicated is the multitude of dimensions and factors that underlie psychopathology and maladaptation. Some disorders, such as Schizophrenia, are probably quite unrelated to ego development, whereas antisocial behavior problems could be quite strongly related. As stated before, what makes this empirical relationship more challenging is that ego development definitions have some overlap with typical psychological problem behaviors and protective abilities.

For those disorders that might be connected to ego development, a fourth model can be introduced. This model suggests key vulnerabilities, risks, and symptom combinations that arise at each ego development position. Our model is probabilistic; that is, when we suggest, for instance, an association between the Conformist ego stage and depression, what we mean is the highest risk of depres-

sion exists for the people at the Conformist ego development stage, whereas for people further from the Conformist stages, this risk is lower.

There are several claims we are making in this introduction before bringing forth the evidence to support them. First, comparisons of clinical and nonclinical samples suggest that, in general, clinical samples have lower means of ego development than nonclinical samples, thus supporting the third model of linkage. Second, we hypothesized that some disorders are more independent of ego development, such as Schizophrenia and those displaying strong associations, such as delinquency and personality disorders. Third, for several disorders more strongly related to ego development, subgroups within the disorder population have been identified. These groups vary slightly in symptom expression and especially in the meaning-making processes used by patients. The evidence suggests that these groups are also closely tied to ego development difference.

PLAN OF THE REVIEW

Along with the scholarly significance of bringing together evidence that offers support to many points of the theoretical debate on the nature of the relationship between the

cognitive-developmental paradigm and clinical research, the practical significance of the topic is also obvious. With a better understanding of which disorders are related to ego development, it becomes possible to make progress in treatment and recovery as a way to support development (especially when there is a developmental delay at hand).

In the next section, we review the literature by diagnosis, using the central way clinical phenomena are divided: the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR)*; American Psychiatric Association, 2000). Many studies were conducted without using this classification system (e.g., using behavior checklists instead), but there is a great deal of overlap between different constructs, and thus it is possible to identify studies that deal with the same symptoms. It is important to recognize that because psychopathology and symptomatology are defined and measured very differently, it is not possible to easily compare studies. Yet we attempt to do that, for the sake of generalization and basing our conclusions on as solid a body of evidence as possible. Thus, while not blurring the lines between, for instance, mood disorders, affective disorders, and depressive symptomatology, we nevertheless consider them in the same subsection.

We begin with a subsection on Conduct Disorder, delinquency, and externalizing behaviors, then move on to personality disorders; following that is a section on mood disorders, internalizing symptoms, and suicidality; then we review studies on anxiety disorders, eating disorders, and alcohol and substance abuse. We conclude with a subsection on defense mechanisms.

In the third section, we concentrate on the relationship between ego development and another end of the mental health spectrum, what many call a positive mental health (e.g., Helson & Srivastava, 2001; Vaillant, 2000). The fourth section covers evidence on the family influences that affect ego development and its relationship to various mental health aspects. The last section are devoted to summary, conclusions, and implications for future research.

EGO DEVELOPMENT AND PSYCHOPATHOLOGY

As a first step we will introduce the measure of ego development and then describe the validity evidence.

Measurement of Ego Development

One of the most prominent features of Loevinger's theory is "the reciprocal relationship between theory and system-

atic data collection" (Hauser, 1993, p. 24). Loevinger and her colleagues did a thorough empirical job making sure that every theoretic idea is grounded in a solid body of evidence and that there is a continual bootstrapping between theory and research.

Washington University Sentence Completion Test (WUSCT) is the instrument used to establish the level of ego development. It is a semiprojective technique that consists of 36 open-ended sentences that the subject has to complete (there are shorter versions, using only 18 or 24 sentences). Two manuals developed by Loevinger and her colleagues (Loevinger & Hy, 1996; Loevinger & Wessler, 1970) serve as help for trained raters scoring WUSCT protocols. Based on hundreds of studies conducted using this instrument since the introduction of the theory, it has been possible to make conclusions concerning reliability and validity of the theory and its measure.

Reliability and Validity

After the first reviews of the 1970s (Hauser, 1976; Loevinger, 1979), hundreds of studies using WUSCT were conducted. Three recent major reviews (Hauser, 1993; Loevinger, 1993; Manners & Durkin, 2001) and numerous less comprehensive papers have brought together evidence in support of the theory and its measure. This section aims at consolidating and integrating evidence from as many sources as possible to draw a comprehensive picture that takes into consideration all the work done in this direction.

Reliability Studies

Test-retest reliability was found to be sufficiently high for total protocol ratings (.72 to .79) and for the item sum scores (.91; Blumentritt, Novy, Gaa, & Liberman, 1996; Loevinger & Wessler, 1970; Redmore & Waldman, 1975) for both normal and clinical populations (Weiss, Zilberg, & Genevro, 1989). Another important reliability aspect, interrater reliability, has been reported as sufficient by virtually every researcher concerned with this problem. Different studies obtained different values of test-retest correlation, yet they were all significantly high, ranging from .70 on individual items to .95 on total protocol ratings (Browning, 1986; Dubow, Huesmann, & Eron, 1987; Hauser et al., 1984; Loevinger & Wessler, 1970; Noam et al., 1984; Novy & Francis, 1992; Snarey & Lydens, 1990; Waugh, 1981; Weiss et al., 1989). As in the case of test-retest reliability, interrater reliability was found to be equally high for psychiatric samples (Weiss et al., 1989).

Split-half reliability was studied by computing correlations between each half and 36-items version and was found significant (Novy & Francis, 1992; Redmore & Waldman, 1975).

Also, internal consistency was reported to be .91 (computed using Cronbach's alpha; Loevinger, 1976; Loevinger & Wessler, 1970); the results were confirmed using psychiatric samples (D. S. Weiss et al., 1989).

Validity Studies

Studies of construct validity of the WUSCT explore the relationship between ego development and related constructs, such as interpersonal behavior, clinical interview data and behaviors, level of defensive functioning, responsibility functioning, and conformity behavior, and were found to be sufficient (Hauser, 1976). External validity was studied extensively, by various means.

Ego level as assessed by WUSCT was found to correlate with the following:

- Ego level as assessed by interviews at about .60 in a rather homogeneous group and .89 in a more variable group (Lucas, 1971; Sutton & Swensen, 1983).
- Other stage tests of personality, for instance, a correlation of about .40 to .60 with Kohlberg's moral judgment test with age partialled out (Lambert, 1972; Sullivan, McCullough, & Stager, 1970).
- Thematic Apperception Test scored for ego development (correlation coefficient of about .80; Sutton & Swensen, 1983).
- Measure of conformity (Hoppe & Loevinger, 1977) and other personality characteristics that, according to Loevinger, were appropriate for certain ego levels (Rozs-nafszky, 1981; Westenberg & Block, 1993).
- Competence as measured by the California Personality Inventory (Helson & Wink, 1987).

Sequentiality studies are an important part of evidence in support of the validity of the theory. In numerous studies, both cross-sectional and longitudinal, Loevinger (1976, 1993) demonstrated that ego level steadily increased during the high school and college years, usually up to the Self-Aware stage, the modal stage of the contemporary adult population. Blasi (1976) and Redmore (1976) have shown that there is an asymmetry of comprehension; that is, people could understand ego levels lower than their own, but not those much higher. Another possible use of similar studies would be to measure average normal growth rates for specific age groups. This was done by some researchers (Redmore & Loevinger, 1979; Westenberg & Gjerde, 1999), but

clearly this is an area of the ego development field that needs more research.

Novy (1990) approached the problem of sequentiality from another perspective. In a complex cross-sectional study, Novy (1993) has found that the maturity factor was clearly progressing with ego stages. We have to keep in mind, though, that maturity is not ego development per se, but is considered by some scholars as one ego dimension (Noam, 1998).

Another problem with sequentiality of ego stages is that the opposite tendency—some people regressing rather than progressing in ego development—has also been reported. This phenomenon has been especially pointed out by Manners and Durkin (2001) as it undermines, at least to some extent, the value of sequentiality studies. More research is due in this area so that we know what are “normal” regression proportions for specific ages and specific groups.

Predictive validity of the WUSCT is assessed by Loevinger (1979) herself as probabilistic rather than rigid. Theoretically, ego development is not supposed to directly predict behavior. In this framework, it was found that ego development could be a good probabilistic predictor of helping, responsibility, and conformity (Loevinger, 1979), and even other behaviors, less directly related to the construct of ego, such as consistency of the use of contraceptives by female adolescents (Hart & Hilton, 1988).

Discriminant validity of WUSCT is usually assessed by exploring correlations between ego development scores and several most closely related variables, that is, intelligence as measured by IQ, fluency as measured by the word count in the WUSCT protocol, and various socioeconomic variables.

Most studies report moderate to high significant correlations (.45 to .50) between WUSCT and IQ (Cramer, 1999; Loevinger & Wessler, 1970). Correlations of fluency and ego level were found to be more moderate, at .31 to .35 (Einstein & Lanning, 1998; Loevinger & Wessler, 1970; McCrae & Costa, 1980), and diverse socioeconomic correlates range from .23 to .51. Thus, ego development was found to correlate with, and differ from, IQ, fluency, and diverse socioeconomic variables.

CONDUCT DISORDERS, DELINQUENCY, AND OTHER EXTERNALIZING BEHAVIORS

In this section, we review the research evidence of the relationship between ego development and the family of mental health problems that include Conduct Disorders,

delinquency, and externalizing symptoms. Although legally adjudged delinquency and clinically defined Conduct Disorders are not synonymous (Quay, 1965), we maintain that the psychological profiles prompting both sets of behaviors are sufficiently similar to allow for meaningful generalizations from the one to the other (e.g., Smetana, 1990). By the same token, delinquency is usually considered a type of externalizing behavior (along with similar phenomena, such as aggression and running away; Noam, Recklitis, & Paget, 1991). Also, the studies cited show that the patterns of relationships with ego development for Conduct Disorder, delinquency, and externalizing behaviors are quite similar. The main difference lies in the measurement tools used. Studies concerned specifically with Conduct Disorder use clinical tools, usually those that correspond to *DSM-IV-TR* (American Psychiatric Association, 2000) criteria. Externalizing symptoms and delinquency are usually measured either by the Child Behavior Checklist (CBCL; Achenbach & Edelbrock, 1987) or by Achenbach's Youth Self-Report (YSR; Achenbach & Edelbrock, 1991). Both measures produce narrow band factors, which then get combined into broadband factors. The broadband factors are similar: externalizing and internalizing symptoms. In the CBCL, internalizing factors include such behaviors and feelings as crying, loneliness, needing to be perfect, and worrying about how others see you. The externalizing factors include arguing, hitting, and destruction of property. In the YSR, the Internalizing scale is a sum of scores for the Withdrawn, Anxious/Depressed, and Somatic Complaints scales. Externalizing is defined as the sum of scores for the Aggressive Behavior and Delinquent scales. Thus, Delinquency can be measured by YSR as one of the narrowband scales. Another way to measure delinquency is with direct behavioral reports, such as case materials for court-directed cases.

We review studies that used those terms separately and then bring the findings together in the summary. We believe this group of mental health problems belongs to the category that has a conceptual and evidential overlap with ego development theory. The characteristics of the lower stages of ego development (particularly egocentrism, poor impulse control, and low empathetic abilities of the Impulsive stage and the hostility of the Self-Protective stage) are also the characteristics of many delinquents.

We start with adolescent studies and then move on to the studies conducted with adult samples. Please note that the tables with details on each study, its sample and measurement, are to be found at the end of the section.

Adolescent Studies

We will now turn to those studies that deal with young people, a populations that is especially vulnerable to delinquency, externalizing, and conduct problems.

Delinquency and Externalizing Behaviors

Frank and Quinlan (1976) studied ego development in delinquent adolescent girls with two comparison groups: girls participating in various recreational programs in an inner-city settlement house and girls who attended regularly a youth development program (YDP). At the time of testing, the delinquents resided in an institution for court-directed cases. Running away, incorrigibility, and sexual delinquency occurred most often among these subjects, whose mean age was 16 years.

Delinquents were split equally between Impulsive and Self-Protective ego stages. As a group, delinquents showed the least mature ego development. The control and YDP subjects did not show significant differences in ego stage, thus bringing the researchers to the conclusion that it is the delinquency factor, not age or social background factors, that primarily accounted for ego development differences.

Hickok (1996) found significant negative correlations ($-.32$) between ego development level and the level of externalizing symptoms as measured by Achenbach's and Edelbrock's (1983) CBCL in a sample of severely emotionally disturbed adolescents (ages 12 to 18). As discussed earlier, externalizing behavior is a combined score of two subscales in the YSR (delinquent and aggressive behavior) and several subscales in the CBCL (hitting, arguing, destruction of property).

In another correlational study of inpatient adolescents, similar findings were obtained: point-biserial negative correlations between ego development (the sample was divided into Preconformist and Conformist ego development groups) and delinquent, aggressive, and externalizing behaviors as measured by the YSR (Achenbach & Edelbrock, 1991) were at a modest level: .17, .20, and .15, respectively (Schneider, 1996).

Ryf (1996) compared two groups of adolescents: a group of psychiatric patients and a matched control group of high school students. Two aspects of her findings are relevant for this review.

First, the hospital group contained a higher percentage of Preconformist subjects (36% as opposed to 20% in the control group) and a lower percentage of Postconformist subjects (18% as opposed to 46 % in the control group).

Second, delinquent behavior for both groups was found to decrease steadily with ego development (from 67.30 for

the Impulsive group to 60.93 for the Conscientious stages group). One seemingly contradictory finding of this study is that aggressive behavior was lowest (56.29) for the Conformist group and higher for both extremes of the sample (60.80 for the Impulsive group and 60.93 for the Conscientious group). Thus, not a linear, but a curvilinear relationship between ego development and aggressiveness was found. This is but one piece of evidence supporting the idea that a curvilinear relationship is possibly in the very nature of ego development.

In another study of a psychiatric adolescent sample, Leong (2000) found delinquent behavior to be equally high for the Impulsive, Self-Protective, and Conformist groups, but much lower for the Postconformist adolescents. The findings on the broadband Externalizing syndrome were completely in line with the other studies presented: Externalizing syndrome was highest for the Impulsive adolescents (65.6), almost as high for the Self-Protective group (63.89), and much lower for the Conformist and Post-conformist groups (59.86 and 59.18, respectively).

Noam et al. (1984) found significant negative correlations between ego development and Externalizing, Internalizing, Aggressive, and Delinquent scales from the CBCL (Achenbach & Edelbrock, 1983) in an adolescent inpatient sample. Yet, in hierarchical multiple regression analyses, after age, gender, and socioeconomic status (SES) were controlled for, only the Externalizing scale kept its significance as a contributor to the variance in ego development. This study, while supporting the strong relationship between ego development and Externalizing behaviors, draws researchers' attention to the importance of using multivariate methods while studying ego development.

To summarize, we note that delinquent behavior was found to have an inverse relationship with ego development by every study (Frank & Quinlan, 1976; Leong, 2000; Noam et al., 1984; Ryf, 1996; Schneider, 1996). A similar pattern was observed for externalizing symptoms and ego development (Hickok, 1996; Noam et al., 1984; Schneider, 1996). This is an important finding, as there are those clinicians who believe that delinquents are often very able to take the perspective of others and are quite evolved but use their significant capacities for devious purposes. The findings on aggressive behavior are somewhat less consistent. The findings presented here suggest that delinquents have not reached levels of development at which they are capable of understanding the world from other people's point of view and that they are developmentally delayed as compared to normative samples.

In order not to be selective and to cite all available, even if contradictory, evidence, we have to mention an unusual study in which a relatively small sample of 42 "normal" African American adolescents participated (Hiraga, 1996). The author explored the relationship between family influences/parenting styles and adolescent ego development. Delinquent and aggressive behaviors were outcome variables, along with ego and moral development. When correlations among outcome variables were obtained, the findings were seemingly in contradiction with the other studies cited: No significant correlations were found between delinquency, aggression, and ego development.

Conduct Disorder and Delinquency: Typologies

Conduct Disorder refers to a variety of maladaptational styles (Hayes & Walker, 1986; Jennings, Kilkenny, & Kohlberg, 1983). The first attempts to distinguish a system of subtypes within this variety were made as early as the 1940s. Many scholars introduced their own typologies, but there are two principles of classification: one based on personality characteristics and another based on age. Even though the research on typology of Conduct Disorder patients and delinquents was not directly related to ego development studies, we show that both classification principles are related to ego development and that the most prominent tendency in delinquency today is to use developmental measurements (particularly WUSCT) to distinguish between the subtypes of delinquents and Conduct Disorder patients.

Early studies on delinquency and personality observed that delinquents were more present oriented and behaved so as to maximize immediate rewards (Barndt & Johnson, 1955; Davids, Kidder, & Reich, 1962). The studies also showed that delinquents had more psychopathic, schizophrenic, and hypomanic tendencies than the average population (Hathaway & Monachesi, 1953, 1961). The next logical step in the same direction was to introduce a classification within delinquent populations that would take personality characteristics into consideration.

The first classification of delinquents was done as early as 1946 by Hewitt and Jenkins, who distinguished three types: unsocialized aggressive, socialized aggressive, and overinhibited delinquents. A series of studies conducted by Quay and colleagues (Quay, 1965; Quay & Blumen, 1963) also arrived at three types, with slight variations. The unsocialized type was called a solitary aggressive, to emphasize this person's acting alone and the aggressiveness of

his or her acts; the socialized type was called subcultural delinquent (this was usually a gang member; thus, the typology stressed the presence of gang subculture with its own norms and role models). The overinhibited type was called neurotic delinquent; this was the least numerous category. There are a few readily available parallels with ego development theory even in the very descriptions of these types. Aggressiveness, hostility, and poor impulse control are by definition characteristics of the Preconformist ego development stages. Group membership and importance of group norms and role modeling are the most prominent characteristics of the Conformist stage of ego development. Thus, we would expect solitary aggressive delinquents to be more delayed in ego development than subcultural delinquents. We show how, in the studies cited later, these parallels were supported by the evidence.

Another classification of the Conduct Disorder and delinquent individuals is based on age. It is also the classification used in *DSM-IV-TR*, where there are two main types: childhood-onset type and adolescent-onset type (with a third category, unspecified onset). By definition, the childhood-onset type starts earlier, before 10 years of age, and is likely to be more persistent and more severe than the adolescent-onset type; also, the disorder that started in childhood is more likely to persist into older age and develop into adult Antisocial Personality Disorder (*DSM-IV-TR*).

Moffitt (1993) developed a similar taxonomy and researched the two types of behaviors, showing the logic and features of the adolescence-limited and life-course-persistent antisocial behaviors.

If we look at these classifications from the viewpoint of ego development theory, we should assume that earlier onset of disorder will be associated with a more severe ego development impairment, so we would expect individuals with childhood-onset (life-course-persistent) disorder to remain at the lower, Preconformist stages of ego development. This dysynchrony, as we know, is related to a variety of maladaptations.

The research on ego development and delinquency supports these conceptual parallels.

Next, we review studies that either used directly the typology of delinquent and Conduct Disorder patients based on the personality characteristics, or whose results imply these theoretically defined parallels.

Solitary Aggressive Type

After Quay's (1965) classification, many diverse attempts to categorize the same diagnostic profiles have been used, including the "psychopathic syndrome" (McCord & McCord, 1956), psychopathic personality (Cleckley,

1964), psychopathic delinquency (Quay, 1965), sociopathic personality (Robins, 1966), undersocialized aggressive (*DSM-III*; American Psychiatric Association, 1980), the sadomasochistic violent juvenile offender (Taylor, 1983), psychopathy (Hare, 1985), and developmental psychopathy (Speicker, 1988). Solitary aggressive type Conduct Disorder is distinguished from other Conduct Disorders by an earlier onset at latency. Consequently, these individuals present with the earliest stages of ego development (Taylor, 1983). Robins reported that children presenting with this type of conduct problem frequently follow a trajectory that leads to Antisocial Personality Disorders in adulthood. A concomitant feature of this outcome is retarded ego development, which likely finds its origins in ego developmental delays starting in early childhood.

Hezel (1968) and Imperio (1975) reported a strong inverse association between ego development and psychopathic factor (Quay, 1965). Even though Hezel's sample included younger subjects, 12- to 16-year-old delinquents as opposed to 14- to 15-year-olds of Imperio's sample, both samples brought the researchers to the same conclusions: that Impulsive ego stage was the modal stage for the participants.

A study by Noam, Paget, Valiant, Borst, and Bartok (1994) aimed at comparing Conduct Disorder, Affective Disorder, and mixed Conduct-Affective Disorder groups on ego development level. In line with the earlier findings, the study found significant group differences, with the Conduct Disorder group consisting almost exclusively of the Preconformist subjects (93% Preconformist and 7% Conformist), whereas the Affective Disorder group had more Conformist subjects (25% Conformist and 76% Preconformist). Mixed disorder groups fell between the two, being closer to the Conduct Disorder group (89% Preconformist, 11 % Conformist). Besides ego development, another variable to best predict disorder group membership was IQ.

In Borst, Noam, and Bartok (1991), two groups of hospitalized psychiatric adolescents were compared: those classified as suicide attempters and nonsuicidal patients. The group of suicidal adolescents had three times more Conformist subjects and four times fewer Conduct Disorder cases than the group of nonsuicidal adolescents, which implies a strong negative relationship between Conduct Disorder diagnosis and Preconformist ego development levels. Thus, both studies found a strong association between Preconformist levels of ego development and Conduct Disorder in adolescent psychiatric patients.

In Noam et al. (1991), which was devoted to the exploration of two different pathways of adolescent psychiatric

patients—those who did progress by at least half an ego level after 9 months of treatment and those who did not progress—statistical analyses revealed significant results relevant to the point of this section. In the progressors group, the percentage of patients diagnosed with Conduct Disorder was 1.5 times less than in the nonprogressors group. Even though the relationship between Conduct Disorder and ego level was not among the research questions of this study, this fact allows us to hypothesize that the Conduct Disorder diagnosis makes it harder for a person to move beyond Preconformist (Impulsive and Self-Protective) stages of ego development. Although Quay's typology was not used in this study, the prevalence of Preconformist functioning among those adolescents points to the solitary aggressive type.

Group Type

Adolescents displaying this disorder have been referred to in the literature under a number of different diagnostic entities, most prominently as subcultural delinquency (Quay, 1965). Although generally presenting with Presocial stages and lower than matched controls, these individuals tend to display greater ego maturity than those with solitary aggressive Conduct Disorders.

The group type Conduct Disorder closely parallels the profile of the lifestyle of a violent juvenile offender defined in Loevingerian terms by Taylor (1983). Disengaged from "normative culture," these offenders join a delinquent peer group or street gang. Adult criminal behavior serves as a source of positive role modeling which is further reinforced through peer support, while finding self-expression through violent behavior. Struggling with both strong dependency needs, in the form of being cared for by others, and inner insecurities, these individuals derive much gratification from delinquent peer group relations. In terms of ego development, Taylor situates these offenders between the Self-Protective and Conformist stages. Imperio (1975) reported that subcultural delinquents (Quay & Parsons, 1971), averaging 15 years of age, display the highest level of ego development of the three Quay delinquency classification types. Clustering between Self-Protective and Conformist stages, some of these adolescents scored as high as the Conscientious ego stage. These findings make perfect sense in the light of Loevinger's theory, as compliance with the group norms is the most prominent characteristic of the Conformist stages of ego development.

Undifferentiated Type

Subjects falling within this category also have been identified as neurotic delinquents (Quay, 1965; *DSM-III-R*, American Psychiatric Association, 1987) and often present

with anxiety-related features. Stemming from underlying conflicts, depressed development with the domain of moral competency may reflect a particularly moral component to their anxiety. Another source of the undifferentiated nature of this type of Conduct Disorder may derive from delinquent behavior, which carries a tendency to act neither exclusively in isolation nor within a peer context. Unfortunately, no specific findings on the individuals diagnosed with this subtype of Conduct Disorder were reported.

The summary of the samples and findings of this section on adolescent ego development and Conduct Disorder and delinquency are represented in Table 19.2.

Adult Studies

Even though ego development represents a scale different from a chronological age scale, there is abundant evidence that ego development does correlate with age, at least through the young adulthood years. The delay in ego development is called *age-stage dysynchrony* and is viewed as a source of additional tension and maladaptation (Noam, 1988). It follows that for adults arrested at the Preconformist stages of ego development, psychological problems characteristic of these stages, such as aggressiveness and poor impulse control, will be even more severe than for adolescents at the same ego level. Yet, probably because adolescents at these levels are more numerous than adults, there are fewer adult studies than adolescent studies. Many of the studies conducted are in institutional settings.

England (1997) compared a group of adult incest offenders with a control group of matched nonoffenders. Incest offenders were significantly lower on ego development than the control group. Specifically, the incest group had three times more individuals at the Impulsive ego stage and two times more individuals at the Self-Protective ego stage than the control group.

In a similar study, Hanson (1999) compared a group of men abusing their spouse/partner with a matched control group of nonabusers. The total violence score dropped significantly with the increase in ego development stage. For the Impulsive ego stage, it was found to be as high as 57.0, but for the Self-Protective, only 18.72; it approximated 3.0 for both Conformist and Self-Aware stages, and went down as low as .722 for the Conscientious stage. This is strong evidence showing the drastic drop in violence as age-stage dysynchrony decreases.

Magee (1984) studied ego development in a small sample of 13 men diagnosed with Antisocial Personality Disorder residing in a forensic evaluation center and charged with serious crimes. The obtained distribution was compared to

TABLE 19.2 Conduct Disorders, Delinquency, and Externalizing Behaviors

Study	N	Gender	Age	Disorder	Results
Frank & Quinlan (1976)	66	F	Mean 16	Delinquency	Delayed ED, modal stage, Impulsive
Hickok (1996)	60	Mixed	12–18	Externalizing	Negative correlation with ED
Schneider (1996)	219	Mixed	13–17	Externalizing	Negative correlation with ED
Ryf (1996)	320	Mixed	15–18	Delinquency	Negative correlation with ED
Leong (2000)	188	Mixed	13–18, mean 15.4	Delinquency, externalizing	Negative correlation with ED
Noam et al. (1984)	114	Mixed	Mean 14.3	Externalizing	Negative correlation with ED
Hiraga (1996)	42	F	Mean 15.9	Delinquency, aggressive	No relationship
Hezel (1968)	N/A	Mixed	12–16	Psychopathic factor	Modal stage, Impulsive; inverse association between ED and psychopathic factor
Imperio (1975)	N/A	Mixed	14–15	Psychopathic factor	Modal stage, impulsive; inverse association between ED and psychopathic factor
Noam, Paget, Valiant, Borst, & Bartok (1994)	269	Mixed	11–17, mean 13.9	Conduct	An association between Preconformist ED and Conduct Disorder
Borst, Noam, & Bartok (1991)	219	Mixed	12–16, mean 14	Conduct	An association between Preconformist ED and Conduct Disorder
Noam, Recklitis, & Paget (1991) ^a	37	Mixed	Mean 13.4	Conduct	An association between Preconformist ED and Conduct Disorder

Note: ED = Ego development.

Loevinger's (1970) normative adult sample. A significantly higher proportion of men scored at the Preconformist ego level than was in Loevinger's sample. While no significant differences were found on the proportions of participants falling into the Conformist and Self-Aware stage, a significantly lower proportion scored at the Conscientious level and higher. We can conclude that although the patients with Antisocial Personality Disorder do score at the Conformist and Self-Aware stages, the tendency for impediment in ego growth is also obvious.

In a similar study of 41 adult male inmates, Angelopoulos (1991) found the Self-Protective ego development stage to be the modal stage for the participants diagnosed with Antisocial Personality Disorder.

Browning (1986) studied problematic ward behavior of inpatient adolescents and young adults (the study is included in this section because of the young adult group who participated in the research) and found a significant inverse relationship ($-.35$ increment in R squared in a hierarchical multiple regression model) between the total number of behavioral incidents and patients' level of ego development. Even though she used a mixed sample (13 to 28 years old) and mixed incidents (e.g., a suicide attempt and a violent act were both counted as incidents, yet the former is found to be more common at the Conformist and higher ego stages, whereas the latter is frequently observed at the two lower stages of ego development, as has been shown else-

where in this section), this is one more piece of evidence supporting the strong inverse relationship between ego development and problematic, action-oriented behaviors.

Wright and Reise (1997) explored the relationship between ego development, personality, and sociosexuality, which is defined as unrestricted sexual behavior, or a tendency to engage in casual, noncommittal sexual relationships. Although not exactly an aspect of mental health, sociosexuality is viewed as a risk factor. Two opposing tendencies were expected: On the one hand, openness to new things and an exploratory attitude characteristic of people at higher levels of ego development might lead to an increase in sociosexuality; on the other hand, better impulse control might lead to a decrease in sociosexuality. These authors believe (and show through their results) that these two tendencies are related to the two aspects of ego development expressed through personality factors: agreeableness and openness to new experiences. Both correlate with ego development: Agreeableness correlates negatively with sociosexuality, and openness correlates positively with sociosexuality.

This study, while supporting the idea of curvilinearity, points out another potential source of it: a multidimensionality of the construct of ego. If different dimensions of ego have different relationships with the same variable (in the earlier example, sociosexuality), this might lead to curvilinearity (or no significant linear relationship) between

this construct and ego development. This study stresses the need to further explore the multidimensional nature of the ego.

Summary and Implications

The evidence presented in this section supports our theory-driven assumption that there is a strong association between Preconformist stages of ego development and the delinquency/Conduct Disorders/externalizing behavior cluster of problems. This is a finding supported by nearly every study conducted.

The studies that had both clinical and normal samples of adolescents found that, uniformly, clinical samples were lower on ego development and higher on delinquency, aggression, and externalizing behaviors. The adults delayed in ego development were found to have a tendency to display poor control over their impulses and behaviors (see also Fisher, 1991; Recklitis, 1993), engaging in various offensive acts, whether incest or unrestricted sexual behavior. In addition to these overarching tendencies, several aspects of the delinquency-mental health relationship revealed are worth further exploration.

First, very few studies used Quay's typology within the Conduct Disorder diagnostic category, distinguishing among the solitary aggressive, subcultural, and neurotic types. Because clinical instruments are better able to capture this distinction, it appears that their use is preferable in the adolescent research. Another important point that has to be made is that ego development is not a simple upward progression: The stages are qualitatively different from one another, which often makes the relationship between ego development and other relevant variables curvilinear. Thus, the use of curvilinear and multivariate methods seems preferable in ego development and mental health research.

Our last conclusion derived from this section is that ego development might be a more complex construct than is now theorized. As we can see from Wright and Reise (1997), the different aspects of the ego can have different relationships with the same variable, thus, stressing the need to focus on different dimensions of the ego.

PERSONALITY DISORDERS

Evidence has been accumulated on personality disorders and ego development, yet only a few studies have covered all personality disorders in their relationship to ego development scale (see also Vincent & Vincent, 1979). This is understandable; considering the number of personality disorders,

to have a representative subgroup of each of them, the sample size should be quite substantial.

Vincent and Castillo (1984) conducted an extensive study with a sample of 400 psychiatric patients who were diagnosed either with one of *DSM-IV* Axis II personality disorders or no personality disorder. The distribution of participants across ego levels is important to this section, thus, we cite the results of the study in full.

No participant scored lower than Self-Protective ego development level or higher than Self-Aware level. The results are organized in Table 19.3, with the personality disorder having the lowest ego mean score beginning the table and the personality disorder with the highest ego mean score ending it.

The lowest ego development was observed in the group diagnosed with Borderline Personality Disorder, and the highest ego development was observed in the group diagnosed with Compulsive Personality Disorder. The authors conclude that, in the personality disorder group, "the majority of individuals below the conformity level were apt to cluster in the personality category of Dramatic, Emotional, or Erratic personality disorder as defined by *DSM-IV*" (Vincent & Castillo, 1984, p. 402).

These findings can be analyzed in several other ways. First, as we can see, most subsamples (excluding the narcissistic subsample that consisted of only one person and thus cannot be analyzed) contain people at all the three ego developmental levels: Self-Protective, Conformist, and Self-Aware. Yet, a few personality disorder groups are restricted to only two ego development levels: The Borderline, Schizoid, and Paranoid Personality Disorder groups consist only of people at Self-Protective and Conformist ego levels, with no one at the Self-Aware ego level. This is

TABLE 19.3 Personality Disorder by Ego Stage

	<i>N</i>	Self-Protective (%)	Conformist (5)	Self-Aware (%)
Borderline	24	67	33	—
Histrionic	75	34	65	1
Schizoid	11	27	73	—
Passive-Aggressive	83	14	83	3
Paranoid	9	11	89	—
Schizotypal	20	15	75	10
Narcissistic	1	—	100	—
Antisocial	7	14	72	14
Dependent	25	8	84	8
Avoidant	41	2	93	5
Compulsive	18	—	89	11

Adapted from "Ego Development and DSM-III Axis II: Personality Disorders," by K. Vincent and I. Castillo, 1984, *Journal of Clinical Psychology*, 40(2), pp. 400–402.

much lower than the normal adult populations (for whom Self-Aware is the modal stage) and even for clinical samples, most of which include at least several subjects scoring beyond the Conformist stage. Thus, we can conclude that Borderline, Schizoid, and Paranoid Personality Disorders are related to a serious impairment in ego development.

On the other hand, the Compulsive Personality Disorder group does not have any subjects who would score below Conformist ego development level. This is not characteristic of adult samples, even of normal adult samples. It seems that the Conformist is the modal stage for the Compulsive Personality Disorder group.

Second, we can compare the personality disorder subsample as a whole to the nondisordered patients in the same study and also to the normative adult and clinical samples (see Table 19.4).

We can conclude that, as a group, people diagnosed with personality disorder scored lower than normal samples and clinical samples. We have to note, though, that “lower” here means not the higher proportion of people at the Preconformist ego levels, as it is, for example, in the delinquency studies, but the lower proportion of people at the ego levels above Conformity. For example, a personality disorder group may be different from the no-disorder group in that it has a similar proportion of individuals at the Preconformist ego level, a higher proportion of the individuals at the Conformist level, and a much lower proportion at the Self-Aware level and beyond. The Conformist ego development level seems to be the modal level for personality disorder patients as a group.

Another study that used the entire range of personality disorder diagnostic categories was conducted not with a clinical sample, but with normal adults: undergraduate students at an urban university. McLauchlin (1997) explored the relationship between the level of ego development and personality pathology measured by the Millon Clinical Multiaxial Inventory III (MCMI-III; Millon, 1983, 1994). Her findings are comparable to those of Vincent and Castillo (1984).

Using a relatively large sample ($N = 249$), McLauchlin (1997) found that some personality types had only one or a few participants. Thus, for the more sound statistical analy-

TABLE 19.5 Mean Ego Levels for Three Personality Types

	Vincent & Castillo (1984)	McLauchlin (1997)
Borderline cluster	3.85	4.54
Preneurotic cluster	4.00	5.02
Neurotic cluster	3.75 (Compulsive only 4.11)	5.07

ses, and also to make a comparison between more severe and less severe personality disorders, McLauchlin divided her personality types into three clusters: the most severe, Borderline cluster (including Borderline, Schizoid, Schizotypal, Avoidant, Aggressive-Sadistic, Antisocial, and Paranoid); a Preneurotic cluster (mild severity disorders, including depressive, self-defeating, and Narcissistic); and the least severe cluster, Neurotic (including Histrionic and Compulsive Personality Disorders).

To make the results of the two studies comparable, we calculated the mean ego level scores for the three personality type clusters for both studies. The results are represented in Table 19.5.

As we can see, the results of the two studies generally coincide, with two major differences. First, the overall mean ego development level of Vincent and Castillo’s sample is lower than the overall ego development level of the McLauchlin sample, which is explained by the fact that, whereas Vincent and Castillo used a clinical sample of psychiatric patients, participants in McLauchlin’s study were undergraduate students, some of whom had the personality type as a trait and a few as a disorder. Second, there is a difference in the low mean ego level for the neurotic cluster in the clinical study. We will not try to explain why the patients diagnosed with Histrionic Personality Disorder in clinical study had such a low mean ego level (3.67), but if we consider this a random finding and take the Histrionic group out of the analysis, the results of the two studies are practically identical.

Generally, it seems that the overall conclusion of this section—that the more severe personality pathology is associated with lower ego development levels—is well supported by the evidence. Genden (1995) studied ego development in a sample of 37 patients at a community mental health agency. He found ego development to predict more severe personality pathology and membership in the “odd personality disorder” cluster, whereas less severe personality pathologies were not found to interact with ego development in that study.

Fineman, Beckwith, and Espinosa (1997) studied ego development in a sample of drug-addicted women with children. Their goal was to establish factors affecting maternal sensitivity in these women. On the whole, the sample consisted of poorly functioning, drug-using women, mostly

TABLE 19.4 Distributions for Personality Disorder and Comparative Samples

	Preconformist (%)	Conformist (%)	Aware (%)
Personality disorder group ($N = 314$)	20	76	4
No personality disorder ($N = 74$)	8	85	7
Loevinger’s normal adults sample	12	33	25
Accumulative normal adults sample	14	16	41
Accumulative clinical adult sample	23	38	25

from lower socioeconomic background; however, their ego development was found to positively correlate with maternal sensitivity. The women also were given a clinical interview, and some of them were diagnosed with MCMI-Axis II personality disorder. Although the relationship between ego development and personality disorder diagnosis was not explored in this study, all personality disorders were found to correlate negatively (the significance wasn't high enough, except for Paranoid Personality Disorder) with maternal sensitivity, which correlated positively (and significantly) with ego development. This suggests a negative association between personality disorder diagnosis and ego development found in the previously cited studies. (This study is also reviewed in the substance abuse section of this chapter.)

Borderline Personality Disorder

Among personality disorders, the borderline personality is the one most frequently studied in relationship to ego development. This interest is natural, if we take into consideration the research on the nature of Borderline Personality Disorder (BPD; e.g., West, Keller, Links, & Patrick, 1993).

Most researchers agree that BPD is primarily a disorder of impulse control (Gunderson & Phillips, 1991; Van Reekum, 1993). Thus, it has a conceptual overlap with ego development theory, with the impulse control dimension being one of the main ego dimensions, and with the prevalence of impulse control problems at the Preconformist ego development level. Also, a relationship between brain dysfunction and brain injuries and BPD was found. Brain injury causes disorders of impulse control, affective disintegration, and cognitive disability (Van Reekum, 1993). Two of these factors—impulse control and cognitive functioning—are closely related to ego development.

Still other studies have found a link, probably of biological origin, between BPD and aggressiveness (Korzekwa, Links, & Steiner, 1993), which is also a prevalent characteristic of individuals at the Preconformist levels of ego development, as many studies cited in this review indicate. In light of these findings, the BPD group being the lowest on ego development among the personality disorder groups (Vincent & Castillo, 1984) is not surprising.

These results were challenged by another study, in which ego development of BPD patients and psychiatric outpatients was compared (Marziali, Field, Classen, & Oleniuk, 1993). In this study, the modal stage for BPD was not Self-Protective, but Self-Aware, which is the modal stage for normal adult samples. Yet, no participant in the study scored above Conscientious ego level, a substantial proportion (10%) scored below Conformist level, and the mean ego de-

velopment score for the group was lower than the mean ego level for the D. S. Weiss et al. (1989) results for psychiatric patients. Thus, although different from the Vincent and Castillo (1984) study, this study confirmed the impairment on ego development for the BPD patients, even in comparison with other clinical samples.

Noam and Houlihan (1990) compared distribution between Preconformist and Conformist ego development stages for a sample of psychiatric adolescents in several diagnostic groups. To clarify the comparison, we use the proportion of participants at the Preconformist ego levels as a simple ego development index. The psychotic group had the lowest ego score (100% at the Preconformist ego levels). The next group was the personality disorder group, diagnosed with either atypical or mixed personality disorder, or BPD (86% of the participants at the Preconformist ego levels, only 14% at the Conformist ego level). All other diagnostic categories (Adjustment Disorder, Anxiety Disorder, Conduct Disorder, Affective Disorder) were found to have lower proportions of participants at the Preconformist ego levels and higher proportions of participants at the Conformist ego level. This finding confirms the conclusion arrived at by other researchers: that personality disorder patients, especially BPD patients, typically score lower on ego development even than other psychiatric patients, and lower than normal controls.

Haimes and Katz (1988) compared ego development findings among a sample of adult outpatients presenting with BPD with those of individuals with eating disorders. Findings suggested that subjects divided evenly between those attaining Impulsive through Conformist stages (53%) and those attaining Self-Aware and Conscientious stages (47%). Borderline subjects scored quite significantly lower.

Horton (2001) studied ego development in three groups of patients: those diagnosed with both BPD and Bulimia Nervosa, the group of bulimics only, and a control group of non-eating disorder, non-personality disorder patients. Not surprisingly, the comorbidity group scored the lowest on ego development, and the control group scored the highest, with the bulimics-only group falling in between. Although partial correlations were not obtained in this study, we see that borderline symptomatology contributed significantly to the low ego development score of borderline/bulimics group. This leads to the conclusion that borderline symptomatology is responsible for the lower ego level score, which is in line with other findings cited in this review.

Summary and Conclusions

Generally, the accumulated evidence so far is rather consistent in suggesting that personality disorders represent an

impairment for the individual's ego development level. This fact is very important for treatment, as one should assume that increasing cognitive-developmental capacities, and in particular ego development, should help patients to overcome their disease.

On the other hand, it seems that different personality disorders have different relationships with ego development. The severity of the disorder is certainly a factor negatively associated with ego development. Thus, the personality disorders in the most severe cluster result in a more pronounced detrimental effect on ego development. Yet, each personality disorder has a unique profile, which must result in a unique relational pathway between those disorders and ego development. This area, potentially fruitful and useful for clinical practice, has not been thoroughly researched yet. The only exception to this is Borderline Personality Disorder, whose conceptual overlaps with the ego development theory have inspired more than a few studies in this area. With a certain degree of confidence, we can conclude that Borderline Personality Disorder usually results in significantly lower ego development levels in both adolescent and adult populations.

MOOD DISORDERS, INTERNALIZING SYMPTOMS, SUICIDALITY

In this section, we review the literature that explores the relationship between ego development and the family of psychological problems that include depression, suicidality, and internalizing symptoms. The rationale for considering those problems in the same section is evident: Basic internalizing and depressive symptoms are various ways of classifying related problems. They are also very different, but there is enough connection that it is possible to review them in one section. Depressive symptoms such as "negative feelings toward self," "loss of emotional attachments (involvement)," "loss of mirth response," "low self-evaluation," "self-blame and self-criticism," "distortion of body image," "increased dependency," "delusions of worthlessness," and "delusions of crime and punishment" (Beck, 1967) each point toward the same deferential tendency. However, although we consider these phenomena in the same subsection, we do not intend to blur the lines dividing them. These are different constructs; moreover, as will be pointed out, even the same construct, such as depression or suicidality, may have different subtypes, and those subtypes would display different relational patterns when considered in their association with ego development.

The relationship between this family of symptoms and ego development is not conceptually clear. On the one hand, because more advanced ego development provides a person with better tools for coping, it is logical to hypothesize that symptoms in general will subside as the person advances along the ego development continuum.

On the other hand, the many features and ideas that make depression possible (such as a clear differentiation between the self and the other, the idea of a standard to measure up to, understanding how other people view one, an ability to experience intellectually defined shame and guilt) are simply lacking at the lower levels of ego development. Thus, another hypothesis here is that the increase in ego development level will actually increase vulnerability to depressive and suicidal thoughts.

Still another view can take into consideration conceptual features of Loevinger's stages and hypothesize a curvilinear relationship between depressive symptomatology and ego development. The expectation is that depressive symptoms will be low at the Preconformist levels when the person lacks the self-differentiation and the self-consciousness necessary for depressive thought, and then will peak at the Conformist level where the other's opinion of one is crucial and painfully important, and then will go down again for the Postconformist people who realize the value of each person's (and their own) uniqueness and thus feel more free and less judgmental toward others and toward themselves.

Last, we cannot totally disregard the studies that found no relationship between ego development and depressive symptomatology. We bring together evidence in support of those positions, and then, through careful analysis of the differences between those groups of evidence, we try to find a solution, even a tentative one, that will need to be tested in future research.

Inverse Relationship between Symptomatology and Ego Development

In support of this position, we cite studies that found a linear decrease in depressive symptomatology, suicidality, or internalizing symptoms for the more advanced ego levels.

Depression

Noam and Houlihan (1990) studied ego development in a sample of early adolescent psychiatric inpatients presenting with various diagnoses. Preconformists constituted a majority of every group: Adjustment, Anxiety, Conduct, Personality, Affective, and Psychotic Disorders. The gen-

eral inference was that the severity of symptomatology was much higher for the Preconformist ego group. The Affective Disorder group displayed the same trend pattern.

Rierdan and Koff (1993) studied ego development and menarcheal timing in female 6th graders. They found that, in one-way comparison, the Preconformist girls scored higher on depression. Yet, for the group of postmenarcheal girls (early menarche), there was a significant group difference for those girls who already had and those who had not yet attained Conformist ego levels. For the latter group, the depression levels were lower. Thus, although early menarche is considered a stressor that might cause depression in girls, the Conformist ego level serves as a protecting factor.

In Ryf's (1996) study, a mixed sample of 160 psychiatric and 160 nonpsychiatric adolescents participated. Two aspects of her findings are relevant for the present discussion. First, when two subsamples were compared, the proportion of Preconformist adolescents was much higher in the psychiatric subsample than in the high school subsample. Second, when the entire sample of 320 was considered, both the narrowband Anxious/Depressed scale means and the broadband Internalizing symptoms means were lower for the Conformist group than for the Preconformist group, thus supporting the inverse relationship between internalizing symptomatology, depression, and ego development.

Griffin (1989) found a significant difference in ego development level for the two groups of high school students: the group that scored at the lower extreme of the Beck Depression Inventory and the group that scored at the higher extreme. The depressed group was found to have significantly lower ego scores. Griffin interpreted her finding as an indicator that severe depression might inhibit ego growth.

Somewhat similar findings were obtained in Snodgrass's 1993 study. She compared three groups: psychiatric patients diagnosed with Major Depressive Disorder, nondepressed psychiatric patients, and a control group of normal adolescents. The control group displayed significantly higher ego development scores than both the depressed and nondepressed psychiatric patients, who did not differ from each other. This study points out that the difference between psychiatric and nonpsychiatric subjects on ego development might be more prominent than the difference between depressed and nondepressed groups within the same subsample.

Those were studies conducted with adolescent samples.

In an adult study, Luthar, Doyle, Suchman, and Mayers (2001) studied parenting experience in a representative sample of women from different socioeconomic backgrounds, including substance abusers, low-SES women who were receiving state assistance, and well-functioning women work-

ing as staff members in an urban university. They found a linear negative correlation between levels of ego development and parental distress. Although not a clinically defined depression, this is clearly a related construct; it was found to have a strong negative relationship with ego development in both bivariate and multiple regression analyses.

Internalizing Symptoms

Borst and Noam (1993) found significant group differences for Preconformist and Conformist adolescents on the Internalizing scale of the YSR. In this clinical sample, the mean Internalizing score was lower for the Conformist group.

In the Noam et al. (1991) study, two groups of hospitalized adolescents were studied: those who progressed at least one-half of an ego development stage and those who did not progress. Both groups showed a decrease in the internalizing symptoms score as measured by Achenbach's YSR broadband scale as a result of the treatment. The significant difference lies in the fact that the mean decrease for the progressors group was about three times as much as the decrease for the nonprogressors group (from 61.87 to 47.40 for the progressors group; 59.50 to 54.27 for the nonprogressors group). The logical interpretation of these findings is that for the psychiatric adolescents, growth in the ego development stage is usually accompanied by a decrease in the internalizing symptoms. It is important to note, however, that treatment played an important role in these results.

In Hickok's (1996) study, a significant negative correlation between ego development and internalizing symptomatology was found for a group of 60 severely emotionally disturbed adolescents.

Suicide

As mentioned, Browning (1986) found that psychiatric ward behaviors correlated significantly with the level of ego development. She found that the total number of suicide attempts went down with the increase in patients' ego level. Thus, her findings indicate a negative relationship between ego level and suicide attempts. This finding should be interpreted with caution, though, as the suicide attempts were not separated from other problematic behaviors, such as accidents and aggressive acts, that are more characteristic of Preconformist levels of ego development.

Linear Increase in Symptomatology with Increase in Ego Development Level

This model of linkage between ego development and symptomatology receives only partial support. Nevertheless, its

rationale is quite strong. With a more complex understanding of oneself and others, the flaws of both are more evident. Such topics, for example, as a keen feeling of responsibility and the main issues of the Conformist persons, such as being tied into the views of others on oneself, the low self-esteem in the face of loss (all potentially present at all levels of development but especially strong at the Conformist levels), a despair at failing to fulfill all these responsibilities, perfectionism, and an existential despair (Noam, 1998)—all found at higher stages of ego development—are nonexistent at the early stages. Yet, as is obvious, these feelings might lead to an increase of self-hate and feelings of one's inadequacy that is closely related to both depression and suicide.

In support of this position, we cite only studies with representative samples that cover the full range of ego development stages, as the linear increase in depressive symptoms for the low end of the ego development continuum—from the Preconformist to Conformist levels—might be an indicator of the curvilinear relationship between depression and ego development.

In a representative sample of creative young musicians and matched controls, Colvin (1994) found that the group of musicians displayed significantly higher ego development levels and also higher incidence of Bipolar Mood Disorder.

Luthar and Quinlan (1993) added a cross-cultural aspect to this discussion. They explored the relationship between ego development and three subscales of the Depressive Experience Questionnaire (Blatt, D'Afflitti, & Quinlan, 1979) in a sample of Indian and American female college students. A positive correlation between the Self-criticism subscale of Depressive Experiences and ego development level was found for Indian women, which nevertheless did not reach a sufficient significance level.

Curvilinear Relationship between Depressive/Internalizing Symptomatology and Ego Development

Many theories point out that a certain level of complexity of thinking is needed for a person to conceive of depressive thought, guilt, and so on. Gibson (1967, p. 100) defines the "prerequisites" for depression:

In depressive ego states the following developmental level has been reached: (a) Perception and memory have developed sufficiently so that "ideal states" experienced in the past are recorded in the psyche and recalled in their absence, (b) hope and longing for a return of the ideal states are present, and (c) some sense of self has developed—This is obviously necessary if one accepts diminished self-esteem as an essential component of depression.

Einstein and Lanning (1998) found a curvilinear relationship between shame (a construct clearly related to depression) and ego development. The feeling of shame was low at the Preconformist and Postconformist levels, and highest at the Conformist level.

In the light of these findings, it is expected that the depressive and internalizing symptoms will peak at the Conformist ego stage, as this is the stage when the group standards are seen as the strongest, and one's failure to meet them the most catastrophic. The next logical assumption is that with more advanced ego development, starting at the Self-Aware stage when one's own view and ideas acquire importance and one has better means of assessing one's life and oneself, the symptomatology might become less severe. We do not mean, of course, that these problems do not exist before and after the Conformist level, but that it is at this level when these issues of standards and failures are the most severe. In support of this view, we cite studies that have found either a curvilinear relationship between depression and ego development for a representative sample, or a linear relationship for the part of the population: a positive correlation between depressive symptoms and ego development for the low-end samples (mostly adolescent samples) or a negative correlation between depressive symptoms and ego development for the high-end samples.

Depression

Borst and Noam (1993) provided multiple findings that are relevant for this subsection. They explored the relationship between suicidality, diagnostic category (Affective Disorder, Conduct Disorder, mixed Conduct-Affective Disorder), and ego development. As a general tendency, a higher proportion of both Affective Disorder patients and suicide attempters were found to function at the Conformist ego level. This supports a linear increase or, because it was a low-end ego development sample, possibly a curvilinear relationship between ego development and depressive symptomatology.

Moreover, after a careful analysis of each subject's responses, the researchers came to the conclusion that suicide attempters were not a homogeneous group. The suicide attempters who still functioned at the Preconformist ego level were classified as "angry-defiant" type, who direct their aggression toward others as well as toward self. Suicide attempters who have already reached the Conformist ego level were classified as "self-blaming" types. These adolescents were more likely to be diagnosed with Affective Disorder. This study refines our views on both depression and suicide

in adolescents and points out the importance of drawing a line more clearly between those two phenomena.

Noam et al. (1994) found statistically significant prevalence of Affective Disorder patients (as opposed to Conduct Disorder and mixed Conduct-Affective Disorders) in the group of inpatient adolescents who have reached the Conformist ego level.

Wilbur et al. (1982) found a positive correlation (controlling for educational level and IQ) between ego development and the sum score for the Beck Depression Inventory for a group of 97 opiate addicts. Because that was a low-end sample, the findings might be interpreted as supporting a curvilinear relationship between depression and ego development.

Gold (1980) explored the relationship between the 10 clinical scales of the MMPI and ego development in normal 14- to 15-year-olds representing a wide range of ego development stages, from Impulsive to Individualistic. The group of Conformist adolescents scored highest on the depression scale, with both Pre- and Postconformist subjects yielding lower depression scores.

Hilmo (1978) reported a small sample of inpatients presenting with unipolar and bipolar depression. These subjects, ranging from 30 to 46 years, ranged from the Self-Protective to the Conscientious stages, with most at the Self-Aware stage. We interpret this finding as support, although a weaker one, for depression being more prevalent among Conformist stages of ego development (Self-Aware stage is classified as Postconformist by some researchers, and as Conformist by others).

Suicidality

Until recently, age was the major developmental dimension considered in the studies of child and adolescent suicidality. It is widely known that children under the age of 12 rarely attempt suicide, yet it constitutes one of the major causes of death among young adults (Hawton, 1986; Shaffer & Fisher, 1981). From the field of developmental psychopathology came a conclusion that young children lack cognitive complexity that makes it less likely to develop full-blown suicide ideation. Yet another step in this line of thinking was to suggest that it is not only cognitive complexity, but, more broadly, aspects of psychological maturity, such as detachment from self, self-hate, and feelings of shame, guilt, and despair that are all signs of a more complex personality organization than that of young children and are hallmarks of a suicidal person. Thus, it was hypothesized that suicide ideation and action will increase with the ego development level (Borst et al., 1991).

In a study of 219 adolescent psychiatric inpatients, significant differences in ego development level were found between the two groups: suicide attempters and nonsuicidal adolescents (Borst & Noam, 1993). Of the Preconformist adolescents, 68% were in the nonsuicidal group, and 32% in the suicidal group. Of the Conformist adolescents, 38% were in the nonsuicidal group, and 62% in the suicidal group. These findings indicate clearly the prevalence of adolescents who have reached Conformist ego development level among suicide attempters. Yet, it indicates that suicide is also possible at earlier developmental levels.

In another study of inpatient adolescents, three diagnostic groups were compared: a Conduct Disorder group, an Affective Disorder group, and a mixed Conduct-Affective Disorder group (Noam et al., 1984). For the Affective Disorder group, the mean ego level was significantly higher than for the other two groups; it was also found to have a significantly higher proportion of suicide attempters (41% of suicide attempters in the Affective Disorder group, only 14% in the Conduct Disorder group; Noam et al., 1994). This finding confirms the association between both Conformist ego levels and suicide, and the suicide and Affective Disorder diagnosis.

No Relationship

Yet another theoretical model of linkage—the one claiming that ego development and mental health are two orthogonal constructs—is supported by studies that found no relationship between ego development and depressive/internalizing symptoms. These are usually studies that hypothesized that the level of depression will be lower for the subjects with higher ego development, yet that failed to support their hypotheses. Dichter (1996) found no significant trend in the relationship between ego development and depression in a large sample of 564 adolescents who attended a public high school in Westchester County, New York, suggesting that “there are no differential patterns of adolescent ego development for level of depression” (Dichter, 1996). In a sample of male and female college students, Wheeler (1994) found “no overall differences according to ego level on the depression or anxiety measures.”

Two important factors need to be taken into consideration while examining this evidence. First, these studies are few relative to the ones that have found evidence in support of the position that the relationship between ego development and depressive/internalizing symptomatology does exist. Second, “no relationship” results might be obtained if the data displaying a curvilinear trend are analyzed with linear tools.

Summary and Conclusions

Depression and Affective Disorders

The findings in this area are most contradictory. All three major views on the linkage between ego development and depression have found some empirical support. The findings are summarized in Table 19.6.

Although the findings in this section are contradictory, a few trends are nevertheless evident. First, depression in clinical and normal populations differs in the degree of severity. Thus, when mixed samples (with both clinical and nonclinical participants) were used, the depression rates for the clinical group were so much higher than for the normal group that it overpowered any differences based on ego development levels.

Second, for homogeneous clinical populations, we conclude that the model of linkage between ego development and a mental health status most in tune with the evidence is a curvilinear relationship: The depressive symptoms are highest for the Conformist ego level. This does, indeed, also make the most theoretical sense if one looks at the features of the Conformist ego development, where anger expression is viewed in negative terms and where fears of loss are great, guilt is significant, and there is so much focus on how others view the self and how one can hurt others (see also Schuessler, 2000; Youngren, 1993). But obviously, no one will argue that there is not depression and internalizing disorders at other points of life. At least one explanation for the increase in depression in the adolescent population, one that has been typically overlooked, is the normative move to the Conformist stage, adding to the risk factors of hormonal changes, family reorganization, peer culture, and so on.

Internalizing Symptoms

Although the Depressive scale is one of the narrowband scales that belong to the broad Internalizing symptoms

scale in the Achenbach system, the conclusions concerning the relationship between Internalizing scale scores and ego development are much clearer than those for the depression subsection. All four studies cited in this review found the inverse relationship, or a linear decrease in Internalizing symptomatology as measured by Achenbach's YSR as people reach Conformist ego development level. The results are summarized in Table 19.7.

The fact that this pattern of relationship between Internalizing scale score and ego development is so different from the relationship between depression (i.e., supposedly, one subscale of the same broadband scale) and ego development poses another problem as to how to interpret this difference. One possible interpretation is that, being a sum of several scores, broadband scales tap into a wider range of internalizing problems, where depression is only one part rather than one particular psychological tendency. The fact that the severity of symptomatology (be it depression or personality disorder) has an inverse relationship with ego development is supported by virtually every study cited in this review.

ANXIETY DISORDERS

Not many studies have been focused on the relationship between ego development and anxiety, in part because anxiety exists from childhood, and it has been harder for researchers to conceptualize it as a developmental set of processes. Yet, more than a few studies have been conducted in this area, and the complexity of the relationship between anxiety and ego development is such that all major models of linkage described in other sections of this chapter have found some evidentiary support.

We bring together evidence on the relationship between ego development and a family of mental health problems

TABLE 19.6 Ego Development and Depression

broadly defined as anxiety. These include clinically diagnosed anxieties and phobias of childhood, adolescence, and adulthood, anxiety as measure by Anxious/Obsessed and Anxious/Depressed scales of Achenbach and Edelbrock's (1983, 1987) CBCL and YSR, and a specific type of adulthood anxiety, death anxiety, as measured by the Death Anxiety Scale (Templer, 1969).

Inverse Relationship

The first hypothesis concerning the relationship between anxiety and ego development assumes an inverse relationship between the two, in which anxiety symptoms subside with ego development growth, particularly in the transition between the two Preconformist and the Conformist ego development levels.

There are at least two studies that show an inverse relationship between anxiety and ego development. Both used clinical adolescent samples, and the decrease in anxiety with ego development they observed happened in transition from Preconformist to Conformist stages of ego development.

In a Noam et al. (1984) study (which was part of a larger study of adolescent psychopathology conducted at McLean Hospital), for a subsample of 49 hospitalized adolescent girls, an inverse relationship was found between the level of ego development and an Anxious/Obsessed scale score from the CBCL. When the background variables (age, gender, and SES) were entered into the equation, the increment of the anxiety scale as one of the predictors for the ego development level was still significant, even though the significance was lower than that found in the bivariate model (Noam et al., 1984).

Ryf (1996) also found a decrease on the Anxious/Depressed scale of the YSR associated with higher, Conformist and Postconformist stages of ego development for the mixed sample of normal and hospitalized adolescents.

Nicolson (1996) administered the WUSCT and the State-Trait Anxiety Index (Spielberger, 1983) to nontraditional graduate students (all older than 35) who attended liberal arts and professional graduate schools in the New York metropolitan area. He found that all students with

lower ego development reported higher rates of state anxiety. This is the only study in this group that used an older sample. It is also important to note that this study did not treat anxiety as a disorder.

Linear Increase

Researchers who expect an increase in anxiety at higher ego development levels base their hypothesis on the assumption that higher ego development also means higher expectations, either on the part of others (for the people on the Conformist ego levels) or on the part of oneself (for the people on the Postconformist ego levels), that can become sources of additional tension and anxiety-inducing stimuli. Especially separation anxiety is very pronounced; also, because anxiety and depression are often associated, one would expect anxiety to increase as depression increases with ego development level in at-risk populations.

At least several studies support this hypothesis, most of them concentrated on a specific type of anxiety: death anxiety.

Barrett (1991) found an increase in two factors of death anxiety in a sample of normal subjects, who were people involved in death education and care of the dying.

Similar findings were obtained in Gutierrez's study (1993). He found that the death anxiety correlated positively with the level of ego development in a sample of 100 community volunteers whose average age was 73 years.

One more finding that constitutes the same trend was found in Geurkink's (1981) study, conducted with a normal sample of college students. She found death anxiety positively related to the level of ego development.

An increase in death anxiety for higher ego development levels found in several studies might seem surprising as, generally, higher ego development levels are thought of as the stages of higher maturity and wisdom that presuppose calm acceptance of reality, including death. The studies just cited seem to suggest that this is not true. Thus, these studies once more draw our attention to the

new vulnerabilities that come into existence only at higher ego development levels.

What is missing from this picture are studies that explore the relationship between ego development and anxieties (other than death anxiety) that are specific of higher ego development levels, which implies a line of inquiry for future research.

The only study that found a linear increase in anxiety (other than death anxiety) is Wilber, Rounsaville, Sugarman, Casey, and Kleber's (1982). The researchers found a significant positive, though not very strong, correlation (.20) between clinically measured phobic anxiety and ego development in a sample of opiate addicts. We might consider this a singular finding, yet, if we take into consideration his sample, a population that, as found by numerous studies, usually score at lower ego development levels, Wilber's finding can be interpreted in the framework of the next approach that we are going to delineate, one that assumes a curvilinear relationship between anxiety and ego development.

Curvilinear Relationship

This approach shares a rationale with similar research on depression and ego development. The reasoning is essentially as follows: Anxiety develops along internalizing pathways, and the pressure to live up to a standard, defined by others but experienced in the self, one of the most anxiety-inducing factors, is highest at the Conformist ego development level.

There are at least several studies supporting this position.

Geurkink (1981) found both state and trait anxiety as measured by the State-Trait Anxiety Inventory to be the highest at the Self-Aware stage of ego development, being lower at both the lower and the higher ends of the ego development continuum.

An indirect support to this hypothesis comes from De Loach (1976), who studied ego development in "neurotic outpatients," resembling what we would currently refer to as General Anxiety Disorder. The subjects ranged in age from 20 to 44 years. The modal stage for these subjects was the Conscientious ego stage, which is higher than the Self-Aware stage, the modal stage for normal adult samples.

These studies coincide in that all of them (including Wilber et al., 1982 study) found evidence in support of the curvilinear relationship between anxiety and ego development. On the other hand, they have important differences. In Wilber's study, the stage of the highest anxiety level was the Conformist stage; for Geurkink (1981) it was the Self-Aware stage; and for De Loach

(1976), the Conscientious stage. The only way to resolve these contradictions is to conduct more studies with normal adult samples with Self-Aware or higher modal ego stages.

No Trend

There are several studies that failed to find any significant association between anxiety and ego development. No significant ego development differences between two groups of women: those who became addicted to sedatives while trying to fight their anxiety and matched controls whose anxiety levels were much lower were found. Waugh and McCaulley (1981) found no significant ego development differences when comparing a sample of clinical patients (among them neurotics, diagnostically linked to Anxiety Disorder) and samples of normal subjects similar to those used in Loevinger and Wessler's (1970) studies establishing the reliability of the WUSCT. Harwell (1987) found no significant correlations between ego development and state and trait anxiety in a volunteer sample of 66 community college women. Farrell (1990) found no relationship between ego development level and trait anxiety in a large (504 participants) sample of women.

These findings might indicate that the relationship between anxiety and ego development is weak, or they might imply that the linear relationship between anxiety and ego development is weak, and thus suggest the use of curvilinear, instead of linear, methods in future research.

Qualitative Differences in Anxiety Disorder Type as Related to Ego Level

One very important trend, emerging in nearly every area of inquiry in the mental health/ego development relationship, is to distinguish subgroups within the population of interest and explore ego development differences among those subgroups. This approach has also been used in anxiety research.

Westenberg (Westenberg, Siebelink, Warmenhoven, & Treffers, 1999) hypothesized the existence of qualitative rather than quantitative differences in anxiety disorder as related to ego level. In a study of 118 children and adolescents (ages 8–18), it was found that two disorder subtypes are related significantly to the ego level group differences. Separation Anxiety Disorder was found to be prevalent at the Preconformist ego levels, and Overanxious Disorder was found much more often at the Conformist ego level.

The authors state:

The clinical features of Separation Anxiety Disorder fit the general description of the Impulsive level. The Impulsive person is characterized by a combination of impulsivity, vulnerability, and dependency. Impulsive persons are preoccupied with aggression in others and self, and they depend on others for protection, care, and guidance generally. The frustration of dependency needs arouses strong negative emotions and is met with help-seeking. Similarly, the worst fear of the SAD patient is to lose the care and protection provided by the major attachment figures. . . . The clinical feature of the Overanxious disorder fit the general description of the Conformist level. The Conformist person follows socially desirable standards for appearance, behavior, and achievements. Conformist individuals live up to expectations, and they blame themselves if they fail to do so. In the same way, persons with OAD are worried about the appropriateness of their own behavior and the adequacy of their own achievements. (p. 1002)

These lines of conceptual reasoning were supported by the evidence. M. Moore (1984) arrived at a similar conclusion when studying attitudes toward death and the relationship between death anxiety and ego development level. She concludes that, conceptually and empirically, "ego development appears to have considerable utility in clarifying attitudinal patterns with respect to death and dying." Yet, she proceeds to suggest that the relationship between death anxiety and ego development is not the one best thought of in quantitative terms. Rather, different meaning patterns of thinking about death (e.g., death as personal failure, natural end, courage, pain, and loneliness) were found in people at different ego developmental levels.

Summary and Conclusions

Generally, anxiety does not belong to the mental health disorders that have conceptual overlaps with any of the dimensions or characteristics that define specific stages of ego development. Thus, there are fewer researchers who hypothesized the relationship between anxiety and ego development to be a fruitful area of exploration. The confirmation of this hypothesis is a much higher percentage of the reviewed studies that found no significant relationship between anxiety and ego development level (5 out of 14 studies, as compared to only 2 out of 23 studies on depression, suicide, and internalizing symptoms).

The studies that were able to record a trend yielded contradictory findings. Of the four studies that found an inverse relationship between anxiety and ego development, three used samples of hospitalized adolescents. Thus, for this specific population, the tendency for anxiety to subside with an increase in ego development seems to be strong.

The most strongly supported model for adult samples seems to be a curvilinear relationship between anxiety and ego development level. The explanation for and the mechanisms of this tendency can only be hypothesized. It seems plausible that although the adults at the lower ego development levels lack the cognitive complexity necessary for construction of anxiety-inducing problems, the adults at higher ego development levels might be better equipped for coping with anxiety.

One surprising (and noncontradictory) finding was that death anxiety increases with levels of ego development (Barrett, 1991; Geurkink, 1981; Gutierrez, 1993); that was found to be true for the samples of older people, as well as for the people working with dying patients, even after controlling for age (Barrett, 1991). This area needs more research, because conceptually, one would expect death anxiety to be lower for the highest ego development stages, where wisdom and wider views on the dialectical nature of life and death become more prominent. One possible explanation for this is that those studies did not involve subjects scored at the highest, Postconformist levels of ego development. Such research is definitely needed to resolve this problem.

EATING DISORDERS

Although eating disorders might have a conceptual overlap with ego development, the research in this area remains scarce. This is unfortunate because, in line with what the evidence in the other areas of mental health suggests, we can expect substantial differences in symptom expression for the bulimic and anorexic patients at different ego development levels. Here, we summarize the existing evidence.

Until recently, Anorexia Nervosa has been most prevalent among educated, middle- and upper-class White women (Bruch, 1973). A similar profile has been found for individuals with Bulimia Nervosa (L. Weiss, Katzman, & Wolchik, 1985).

Common to both disorders are salient concerns about interpersonal relationships, meeting others' expectations and retaining others' approval. The critical importance of personal appearance both before others and oneself emerges as a further preoccupation among those with eating disorders. Also of import is the growing differentiation and awareness of the self as an object of self-examination and as discrete from others in interpersonal relationships. Finally, as differentiation of self from others becomes more fully integrated with a larger social perspective, the conflict between dependence and independence grows in significance. Many of

these psychological foci are tied to the Conformist and Self-Aware ego development stages. According to the expectations, the modal stage for both anorexics and bulimics is the Self-Aware stage, a finding that is yet to be acknowledged and used in the eating disorders field.

Anorexia Nervosa

Among anorexics, the issue of self-differentiation from others is especially acute. Along these lines, Bruch (1973, p. 102) has observed that anorexics “experienced their bodies as not being truly their own, as being under the influence of others. They felt that they had no control over their bodies and its functions.”

A central issue among anorexics relates to social isolation due to extreme feelings of awkwardness and anxiety in interpersonal situations. Corresponding to this issue is a “self-consciousness” and “discomfort” noted in social situations by individuals at the Self-Aware stage.

According to these considerations, we should expect Anorexia Nervosa to be most prominent among individuals at the Self-Aware ego development stage. Yet, as is true about other mental health areas, the prevalence of a disorder at a certain ego stage (e.g., the relationship between depression and Conformist ego stage) does not mean the exclusive occurrence of a given disorder at a given ego stage. Rather, we are referring to the highest probability of its occurrence at this stage, while the probability of it at the consecutive (higher and lower) stages is less. The findings of several studies seem to support this assumption.

Swift, Camp, Bushnell, and Bargman (1984) found that the majority (55.2%) of their subjects (anorexic patients) attained the Self-Aware stage. Yet, this does not lead us to the conclusion that there is a special association between the disorder and the Self-Aware ego stage, as this is also the modal stage for normal adult populations.

To clarify this issue, we compared those percentages from Loevinger and Wessler’s (1970) normative sample, which showed 25% of the subjects scored at the Self-

Aware stage, and 23% at the Conscientious stage. The percentage of anorexic subjects who scored at the Self-Aware stage is noticeably higher than Loevinger and Wessler’s (1970) normative sample of adults, whereas the percentage of subjects who scored at the Conscientious ego development level are quite similar to those from Loevinger and Wessler’s (1970) normative sample. This suggests that perhaps the Self-Aware stage may be most common among anorexic individuals, and that further study can prove valuable.

In the same line are Luce’s (1983) findings. On a sample of female adult hospitalized inpatients, she has shown that the three groups (anorexics, bulimics, and bulimic anorexics) did not differ from each other on the mean level of ego development, yet scored higher even than the Self-Aware stage, which, as is shown elsewhere, is the modal stage for normal adult populations.

Haimes and Katz (1988) examined sexual and social maturity and ego development (as a measure of social conformity) in restricting anorexics, bulimics, and women with Borderline Personality Disorder. Restrictor anorexics averaged 26 years of age, with an average age of onset at 18 years. Findings again pointed predominantly to the Self-Aware and Conscientious stages.

To fully confirm this finding while taking into consideration other factors, we would need more research in this area of exploration.

Bulimia Nervosa

Teusch (1988) studied ego development in bulimic outpatients age 18 to 39 years. Displaying a pattern similar to the anorexia studies, the majority of participants in this study attained Self-Aware (52.5%) and Conscientious (35%) stages.

We compared these percentages with those from Loevinger and Wessler’s (1970) normative sample which reported 25% at the Self-Aware stage and 23% at the Conscientious stage as shown in Table 19.8. This comparison not only illustrates the prevalence of bulimia at the

TABLE 19.8 Comparison of Bulimic Outpatients to Normative Sample

Study	Self-Aware (%)	Conscientious (%)
Teusch (1988)	52.5	35
Loevinger & Wessler (1970) (<i>N</i> = 1,640)	25.0	23.0
Normal adult accumulative sample (<i>N</i> = 1,700)	41.5	19.6
Clinical adult accumulative sample (<i>N</i> = 1,224)	25.1	9.7

Self-Aware stage of ego development but also suggests a noteworthy association between bulimia and the Conscientious ego stage.

As the association between the Self-Aware stage of ego development and eating disorders seems both empirically and theoretically solid, some researchers went further to explore the causative factors that might have led to the disorder (e.g., Billing, 1987; Kutcher, 1989).

Various studies showed that “women with unhealthy eating attitudes tended to overeat following exposure to particular types of threat” (Waller & Meyer, 1997, p. 299). Among these threats were the loss of a relationship (Pyle, Mitchell, & Eckert, 1981), victimization (Root & Fallon, 1989), fear of abandonment (Patton, 1992), and negative evaluation of self (Heatherton & Baumeister, 1991). These preoccupations can be characteristic of several ego stages, especially Conformist and Self-Aware. The parallel is evident, yet, more research is needed to clarify this issue, including controlled intervention studies that simultaneously treat the eating disorder and support ego development.

Qualitative Differences within the Eating Disordered Population

As we pointed out in other sections, a prominent line of contemporary research in the area concentrates not only on correlations between ego development and specific disorder scales, but on the qualitative differences within the patients with the disorder as related to the ego development level.

Horton (2001) hypothesized that there would be differences within the bulimic population based on the Borderline Personality Disorder diagnosis. The hypothesis that individuals with Bulimia Nervosa and BPD functioned at lower ego development levels than the individuals with the eating disorder alone or than those in the control group was based on Smith, Burke, Nawn, and Reif's (1991) findings.

To make the distinction clearer, Horton (2001, p. 42) refers to Favazza, DeRosear, and Conterio (1989), who suggested that “self-mutilation and eating pathology might be a part of a pathological impulse disorder, which they call ‘deliberate self-harm syndrome.’” Thus, she suggests a distinction between the more impulsive groups of bulimics (who function at lower ego developmental levels) and more rational ones.

To support this hypothesis, Horton (2001) divided her 71 women-participants into three groups: group 1 ($n = 27$),

Bulimia Nervosa without BPD, group 2 ($n = 19$), Bulimia Nervosa and BPD, and group 3 ($n = 25$), the non-eating disorder, non-personality disorder group. All three groups were significantly different on the ego development level. The lowest ego level (mean 3.78) was found among the bulimic and BPD group. We can say that the members of this group were divided mostly between the Self-Protective (E3) and Conformist (E4) ego stages. The bulimic-only group had a mean of 4.48. We assume that the members of this group divided approximately equally between Self-Aware and Conformist ego levels. This finding both supports and undermines the idea that the modal stage for bulimics is the Self-Aware stage. It suggests that there are many bulimics functioning at this stage, but even for the more rational, nonimpulsive bulimics, this is the highest among the two modal stages. Impulsive bulimics are found to function at the lower ego stages. To further explain this difference, Horton points out the negative correlation between ego development and the Self-Harm Function score, a score that is highest for the comorbidity (Bulimia and BPS) group.

There are at least two aspects in which this study is important. First, it distinguishes between the two qualitatively different groups within the diagnostic category, the groups that differ mostly based on the subjects' ego development scores. Second, it employs multivariate methods, introducing variables that clarify the relationship between ego development and eating disorder.

Farrell (1990) showed that in a representative sample of 540 women, ego development was inversely related to binge eating. Thus, binge eating as an impulsive aspect of an eating disorder was more prevalent among lower ego developmental levels. We can conclude that binge eating is a more prevalent aspect of eating pathology in the impulsive deliberate self-harm type.

Kennedy (1994) attempted to take a broader perspective on the relationship between eating disorders and ego development. She compared two age cohorts, middle-aged mothers and their college-age daughters, and hypothesized that the changed role of women in contemporary society (in other words, an increase in pressure as much as in freedom) might be responsible for the recent increase in eating pathology. For the mothers, she found that eating disorders were negatively related to ego development level. In other words, among the middle-aged women, those who failed to achieve higher ego development levels were more likely to exhibit eating pathologies, thus, suggesting the deliberate impulsive self-harm type of eating behaviors. For the daughters, contemporary

young women, this pattern did not hold, suggesting that the daughters fell more into the more rational type who are higher on ego development. This study further emphasizes the within-diagnosis differences among eating disordered women according to ego level group and introduces broader societal factors that might be related to this dichotomy.

Summary and Conclusions

This evidence, though scarce, points out several tendencies that call for further exploration.

Generally, eating disorder patients are mostly White middle-class women with a high SES and higher ego development levels. The modal stage for both bulimics and anorexics is the Self-Aware ego development stage. There is also a solid proportion of eating disorder subjects who attain the Conscientious ego stage.

On the other hand, if an eating disorder is severe, and especially if it is combined with another pathology (such as BPD or depression), it might inhibit the person's ego growth. Thus, a proportion of ego development subjects do score at lower ego development levels. These subjects seem to be more often bulimics than anorexics, and they have a destructive self-harm tendency that is an expression of impulsivity that thus makes them gravitate to the lower ego development levels. We might hypothesize that the two tendencies—a perfectionistic striving for self-improvement common for the Self-Aware and Conscientious ego levels, and the impulsivity of Preconformist ego levels—might cause the ego dichotomy, a tendency that has not been fully explored yet and is currently a point of conceptual debate (Holt, 1998; Noam, 1993, 1998).

ALCOHOL AND SUBSTANCE ABUSE

The relationship between alcohol/drug abuse and ego development is a potentially rich topic that also has not received enough attention from the research community. There are numerous reasons for this. The conceptual parallels between this problem area and ego development are too complex to generate clear, testable hypotheses. On the one hand, we should expect ego development to have a strong association with such an aspect of substance abuse as poor self-control, which, we know, is lowest at the Preconformist stages of ego development. On the other hand, alcohol and substance abuse is often a reaction to one's failure to meet one's own and societal expectations, which become

explicit topics only at the Conformist stages of ego development. Also, the view of alcohol and drug use that might affect a person's consumption and behavior are very different for different social groups. For instance, whereas in the traditionally oriented middle-class circles drug and alcohol use are at least frowned upon, in the younger groups, and in such specific communities as hippies (discussed later), the use of some drugs, especially marijuana, is not necessarily a deviation from the norm. Clearly, drug and alcohol use is not unitary and the causes are many. Thus, the relationship with ego development should not be expected to be a simple one. However, it is hard to imagine that the meaning system people use to interpret themselves and others would not have a potential relationship with the use of drugs and alcohol, the situations that trigger desires for these substances, and the supports that would be especially efficacious.

We would also expect that the patterns of relationships with ego development will be different not only for different social groups, but for different drug types. So far, as will be evident in our discussion, the only drug type that received special research attention is opioid drugs.

Opioid Abuse and Dependence

Opiate users have been found to struggle with underlying depression, alcoholism, and/or sociopathy (Rounsaville, Weissman, Kleber, & Wilber, 1982). Kurland, Turek, Brown, and Wagman (1976) have suggested that opiate addicts suffer from fundamental feelings of alienation from others and perhaps also struggle with the formation of "adult identity." They use the drug as a "replacement for mature interpersonal relationships and adult sexuality, as a defense against experiences of intense anxiety, depression, and aggression, or as a way of avoiding intolerable somatic and psychic pain" (Blatt, Berman, et al., 1984, p. 156), as relief from inward rage, self-reproach, and despair, and as a means of restoration of self-confidence (Khantzian, 1974; Rado, 1957).

Blatt, Berman, et al. (1984) studied ego development in a relatively homogeneous (young, male, single, White, high school-educated or less, and from lower socioeconomic levels) sample of 99 opiate addicts seeking treatment at a drug dependence unit. Twenty-nine CETA (Comprehensive Employment and Training Act program) applicants, all chronically unemployed and impoverished yet without a history of drug use, were matched with opiate addicts for gender, race, educational level, and social class, constituted a control group. The researchers also used two other control samples, of 100 noncollege males and an equal number of

noncollege females. Modal stage for opiate addicts was Ritual-Transitional (Delta-3), a transitional stage between Self-Protective and Conformist and, in the new classification, usually merged with the Self-Protective stage. It is lower than the modal stage for CETA applicants (Conformist) or the modal stage of both normal samples (Self-Aware). Also, the mean ego level is lower for the opiate addicts as a sample than for the three other samples. Not surprisingly, the percentage of opiate addicts at the higher ego stages (26% at each Conformist and Self-Aware stages) implies that it is possible to be an opiate addict and yet function at higher ego development levels.

Another intriguing aspect of the same problem is a strong association between opiate addiction and depressive tendencies. This view is supported by numerous studies and research reports (see Blatt, Rounsaville, Eyre, & Wilber, 1984, for a review) suggesting that depression (and dysfunctional attempts to fight Affective Disorders) may be a central issue in opiate addiction (Blatt, Rounsaville, et al., 1984). This creates a contradiction. On the one hand, the Self-Protective stage seems to be the modal stage for opiate addicts. On the other hand, the association between opiate addiction and depression would lead us to expect that the modal stage for depression—Conformist ego stage—is also the modal stage for opiate addicts. A possible solution to this problem would be to expect that there might be qualitative differences within the opiate user population: Those at the Preconformist ego development levels might be different from those who score at the Conformist ego level (this subpopulation might also have the highest depression scores) and Postconformist ego development levels.

This is the hypothesis that has been tested in another study by Blatt and Berman (1990).

A sample of 53 opiate addicts were given a series of measurements, including the WUSCT, Wechsler Adult Intelligence Test, Bellak Ego Functions Interview, and the Rorschach. Cluster analysis was used with the goal to test the homogeneity of the opiate addicts sample. Three subgroups of opiate addicts were found, all significantly different on many of the 11 variables entered into analysis.

The first cluster, characterized by impaired ego functioning and thought disorders, contained 30% of the sample and was lowest on ego development. The second cluster, a little higher on ego development, contained 42% of the sample and was characterized by impaired interpersonal relationship and affective lability. The third subgroup contained 28% of the sample and was characterized by lower levels of activity (a lower number of responses on the

Rorschach) yet better reality testing, indication of better interpersonal relationships and more effective defenses. This subsample also had the highest ego development level.

This study, though following the most promising paradigm of dividing populations in question into different subgroups, nevertheless did not include a depression measure in the set of the variables studied.

Wilber et al. (1982) used the same sample of opiate addicts and CETA applicants to explore the relationship between ego development, substance abuse, and clinical assessment results (the Beck Depression Inventory; Beck & Beck, 1972). While opiate addicts were lower than CETA applicants on ego development level (as indicated in Blatt et al.'s 1984 paper), in opiate addicts ego development was found to correlate negatively with the severity of drug use and positively with several clinical diagnoses: somatization, phobic anxiety, psychoticism, depression, and neuroticism. This study, while exploring the relationship between depression and opiate addiction, did not distinguish among the subgroups within the opiate addict population.

The next step in this line of investigation was to explore the relationship between the three groups of factors—ego development, drug addiction, and depression levels—in their interaction with each other. This was done in another study, yet it did not concentrate only on opiate addiction.

Other Substance Abuse Studies

Luthar et al. (2001) studied ego development and parental experiences in a diverse sample of drug-abusing women. The participants were from different socioeconomic backgrounds. Opiate addicts, women with low SES, and minorities were represented in the sample. The results indicated that the level of ego development correlated significantly (and negatively) with the severity of substance abuse and positively with parental satisfaction. This was the only study that explored the relationship between ego development, distress (not depression, yet a related construct), and substance abuse. For both low and high ego development groups, the distress and substance abuse were inversely related; that is, the people in distress had a much higher chance to be substance abusers, or substance abusers had much higher distress levels. This clearly confirms the other findings cited (Blatt & Berman, 1990; Wilber et al., 1984). The researchers went one step further and explored the interaction between the three groups of factors. They found that the association between distress and severity of abuse was stronger for the high ego level group. The low ego level group experienced a relatively

high level of distress independently of whether they were or were not substance abusers. The high ego development group experienced a low level of distress if they did not abuse drugs and a high level of distress if they did. Thus, the high ego development, non-drug-abusing group had the lowest distress and drug abuse put even mature ego development women at the risk of high distress.

In Fineman et al. (1997), a group of drug-abusing women from poor socioeconomic backgrounds was found to have a very large proportion of subjects at the Preconformist levels of ego development (41%) and an unusually low proportion for adult populations of subjects at the Postconformist (E6 and up) levels of ego development (4%). These women, we have to conclude, were significantly delayed in ego development.

Even though opioids are relatively strong drugs, and the severity of abuse has been found to correlate inversely with ego development in every study that has asked this research question, it is not surprising that the modal stage among opiate addicts is the Self-Protective ego stage. Yet, even in the opiate abuser samples, there were substantial proportions of subjects who scored at higher ego development levels. Several other studies have obtained similar results.

Haan, Stroud, and Holstein (1973) studied moral and ego processes in a relatively small ($N = 58$) sample of hippies between age 17 and 35. This was a nontraditional sample consisting of people of higher than average intelligence who chose "a socially dissident, morally uncertain, and personally hazardous" (p. 609) way of living. Drug use was substantial in that community, with marijuana and psychedelic drugs used by almost everybody, along with heavy use of amphetamines. Yet, we should note, there are no data as to whether those people were real drug addicts needing help. The ego scores distribution for this sample is compared with the Loevinger normative data. The study found a lower percentage of people at both the Preconformist and Conformist ego stages combined (12%), however, the vast majority presented with higher ego stages.

Another consideration that the researchers studying ego development in drug users might find useful is that for different drug types, different relationships with ego development might be found.

Hawley (1995) studied ego development and substance abuse in a small sample of 30 volunteers recruited from the patients of the counseling office in a major urban university. The researcher made a clear distinction between those participants who used traditional drugs (with no distinction among the drugs; all participants using them were labeled substance users) and the users of psychotropic medication, a less traditional type of drug. No substance abuser scored

higher than the Conformist ego development level, with the Self-Protective being the modal stage for substance abusers. Yet, no ego development differences were found among psychotropic medication users. Among six of them, two were at the Self-Protective stage, one at the Conformist, one at the Self-Aware, one at the Conscientious, and one at the Individualistic stage of ego development.

Santina (1998) set a goal to find the most powerful predictors for severe substance abuse. The participants in her study were 50 residents (46 males and 4 females) of a most-restricted-order drug rehabilitation program who were polysubstance-addicted and represented the most severe levels of substance addiction. Among the independent variables were object relations (with subscales of alienation, egocentricity, insecure attachment, and social incompetence), ego development, experienced level of childhood trauma, psychopathology, and difficulty discerning and labeling emotions.

Using discriminant analysis, it was found that the best predictor for substance abuse was insecure attachment. Less powerful predictors were alienation, difficulty discerning and labeling emotions, level of childhood trauma, social incompetence, and, finally, psychopathology. Egocentricity and ego development failed to enter into the equation, indicating that scores on these variables did not account for any unique variance among the groups that were not already explained by the variance noted earlier.

The most logical interpretation of these results is that low ego development alone does not lead to substance abuse (see also Guerra, 1991; Pingalore, 1982); rather, both ego development and substance abuse might be influenced by early experiences, in this case, insecurity of attachment. Several researchers studied ego development in relationship to rehabilitational treatment results. The hypothesis was that ego development, while not preventing individuals from substance abuse, provides a better coping response repertoire and thus makes rehabilitation treatment results more likely to be positive. A study was conducted with the residents of a drug abuse rehabilitation program who were administered the WUSCT at the entrance and exit points of the treatment (Loiacono, 1995). The exit group had a significantly higher ego development mean, which supports the hypothesis.

Colan (1988) explored the reaction to treatment in a sample of adult substance abusers undergoing an 18- to 28-day inpatient treatment program. The sample contained all three groups of ego development levels: Preconformists, Conformists, and Postconformists. It was hypothesized that the Postconformist patients would benefit more from the treatment and show greater improvement than Preconformist

and Conformist patients. The hypothesis was partially confirmed: The Postconformist group showed significantly greater improvement in the two areas of self-concept: self-deprecation and self-confidence. There were no significant differences in the other areas.

Thus, the hypothesis that higher ego development stages provide individuals with better coping strategies has been tentatively confirmed, yet more studies are needed in this area (see also Furstenberg, 1984). And we have to admit that several studies failed to obtain significant group differences on ego development level for drug users and matched controls. Flesher (1986) compared alcohol and drug abusers, day laborers, business and banking analysts, entrepreneurs, and university professors. No significant between-group differences were found, yet the mean ego level for this heterogeneous sample was lower than the normative data in the field indicate is average for normal adult populations.

Menicucci (1983) failed to find significant group differences on ego development when comparing a small sample of treatment facility patients and matched controls. No significant differences on ego development level between a group of sedative-abusing women and matched controls were found. However, the drug-abusing group was found to have a higher frequency of anxiety and neuroticism reports. No attempts were made to build a complex model that would explore three factors simultaneously.

Alcohol Abuse

The onset and course of alcohol-related disorders is gender-dependent. Onset among men occurs in late adolescence or early 20s and begins later among women (*DSM-III-R*). With chronicity, underlying feelings of guilt, shame, anxiety, worthlessness, remorse, and depression become more evident. Incidents of amnesia, for example, evoke fears of having harmed or miscondacted oneself while intoxicated (Woodruff, Goodwin, & Guze, 1974). This concern for others reflects underlying structures of social reciprocity and psychological mindedness (see also Moore, 1983). Johnson (1983) and Scott (1980) describe one motive for alcohol consumption as a form of self-esteem regulation. Johnson further describes alcoholics' tendency toward "harsh, punishing, self-directed guilt" following fits of impotent rage.

Rozsnafszky (1981) explored the relationship between the levels of ego development and Q-sort personality ratings in two groups: a group of 65 alcoholics and a control group of 26 medical patients. The modal ego stage for both alcoholics and controls was the Self-Aware ego stage, yet a

much higher percentage of alcoholics scored at the Preconformist ego development levels (32% as compared with only 12% of the medical patients), and a lower percentage of alcoholics attained Postconformist developmental levels (15%) than the controls (23%). These findings are similar to the opiate addict findings and leave some space for interpretations. On the one hand, it is evident that alcoholics have a higher chance of scoring at the Preconformist stages of ego development, which is hardly surprising as impulsivity and poor self-control are characteristics of both alcoholic populations and the lower levels of ego development. On the other hand, a rather substantive percentage of alcoholics who scored at the Conformist stage and higher makes us wonder what are the differences between those two groups of alcoholics: Whether the severity of the addiction, or alcohol consumption, patterns are different for Postconformist than they are for the Preconformist, impulsive alcoholics is a question that has not been addressed in this study. Unfortunately, much less evidence is available in this area of exploration, which also leaves an open space for future research. Particularly, a study that would address the subgroups within alcoholic populations based on ego development and (possibly) in relationship to psychopathology would shed light on the developmental differences within adult alcoholic populations and perhaps offer some treatment insights.

Adolescent Studies

The studies that address ego development in adolescent substance and alcohol abusers have to take into consideration the fact that the Self-Protective stage of ego development, the modal stage for adult heavy substance abusers, is also the modal stage for both clinical and normal adolescent samples. So the ego development impairment for adolescent substance abusers will probably be harder to test, at least for younger adolescents.

Geiger (1990) studied ego development in a sample of 50 hospitalized chemically dependent adolescents. The modal ego development stage for them was Self-Protective, yet, as was noted earlier, this finding in itself does not prove that alcohol and substance abuse in adolescents is associated with ego development impairment. To test impairment in other than ego development areas, the researchers used additional variables and found problems in reality testing, poorly managed affect, low self-esteem, and maladaptive interpersonal relationships.

To test the hypothesis that substance abuse in adolescents is related to the delay in ego development, researchers would need to compare proportions of Preconformist

adolescents who are substance abusers with those in a non-abusing group. This was done in Noam et al. (1994). These researchers found prevalence of alcohol use and dependence and cannabis use and dependence in the group of Conduct Disorder psychiatric adolescents who were predominantly at the Preconformist ego development levels. The proportion of Preconformist adolescents and substance abuse score was significantly lower for the Affective Disorder group.

Du Mont (1998) studied the “detrimental” influence of early menarche on educational and personality development of adolescent girls. In her complex study, level of ego development, empathy, family warmth, interparental conflict, and depression were used as independent variables hypothesized to influence youths’ risk behaviors, such as cigarettes, alcohol and drug use, early coital debut, and low educational attainment. Early pubertal development was found to be a risk factor that promoted risk behaviors, including alcohol and drug use, and higher depression levels. It was also positively associated with the level of ego development. Ego development was found to be associated negatively with depression and risk behaviors. Thus, a complex model emerged. In this model, two positively associated factors—early puberty and ego development—had conflicting influences (e.g., ego development positive, and puberty negative) on the adolescents’ levels of depression and risk behaviors. This study, while confirming a negative association between ego development and adolescent substance abuse, also supports the use of multivariate methods as preferable in ego development research.

Summary and Conclusions

The main conclusion of this subsection of the review is that there are many more problematic areas in the field of ego development and alcohol and drug use than there are studies that cover them. From the evidence cited, only a few conclusions can be drawn.

First, the Self-Protective might be the modal stage for heavy adult drug and alcohol users, yet people at all ego development stages abuse drugs. Some studies indicate the Self-Aware as the modal stage, with the percentage of subjects on it higher than in normative adult samples.

Second, the evidence suggests a need to make a distinction between specific drug-using groups. As was shown, the difference between the hippies who scored higher than normative adult samples and opiate addicts, mostly at the Self-Protective ego development stage, is substantial. Another distinction that needs to be made (and this is in line

with the research in every other area of the mental health-ego development relationship) is the differences between subgroups within problematic populations, which, in this particular area, was done in only one study that involved an opiate addict sample.

Another prominent line of research seems to be a relationship between drug use, depression, and inability to be in intimate relationships that possibly can be traced to childhood and attachment mode. Those factors need to be built into research models when studying drug use and ego development. Last, the only noncontradictory finding that has been obtained by every researcher who is concerned with this problem set is that ego development always correlates negatively with the severity of abuse.

Defense Mechanisms

In the Loevingerian framework, it is logical to assume that the way of coping with negative emotions will be different for different ego development stages. It is not surprising, therefore, that the findings on the relationship between the level of ego development and the use of defense mechanisms strongly suggest the relationship between the two.

Most of the studies conducted in this area used the Defense Mechanisms Inventory (DMI; Gleser & Ihilevich, 1969; Ihilevich & Gleser, 1971, 1986). Among the major defenses, turning-against-object (TAO), turning-against-self (TAS), and projection are considered less mature defense mechanisms as they presuppose aggression and an immature distortion of reality. Principalization and reversal, on the other hand, are more intellectual and less aggressive defenses and are considered more mature.

Thus, we should expect the use of TAO, TAS, and projection to decrease with ego development, especially in transition from Preconformist to Conformist ego levels, whereas the use of principalization and reversal should increase. This hypothesis was supported by nearly every study conducted in this area.

In a time-series study of 37 psychiatric adolescent patients, those subjects who displayed progress in ego development over a period of 9 months also demonstrated significant changes in their use of defense mechanisms. With the transition from Preconformist to the Conformist stages of ego development, the use of TAO, TAS, and projection defenses were significantly lowered, and the use of principalization and reversal increased (Noam et al., 1991).

This confirms the earlier findings by Levit (1989), who used a normal sample and found that the use of TAO

is inversely related to ego development. Hickok (1996) found significant negative correlations between ego development and TAO and projection; a significant positive correlation was found between ego development level and principalization.

In a study of adolescent girls who were patients at a residential treatment center, Borst and Noam (1993) explored the relationship between ego development, several scales of the YSR, clinical diagnoses, suicidality measurement, and defense mechanisms as measured by DMI (Gleser & Ihilevich, 1969; Ihilevich & Gleser, 1986). The results they obtained were quite in line with the other findings. They found TAO to be higher at the Preconformist ego levels and lower at the Conformist ego level (significance at $p < .01$), even more for the suicidal group than for the nonsuicidal group ($F = 6.99$ for the nonsuicidal group, as compared to $F = 10.81$ for the suicidal group; in both cases, $p < .01$). Projection displayed the same pattern, only the difference between the Pre- and Postconformist groups (and thus the significance of the results) was slightly lower here than for the TAO, and there were no significant group differences between the suicidal and nonsuicidal Conformists in the use of this defense. The use of principalization displayed the reverse tendency: It was found to be higher for the Conformist than for the Preconformist girls. In the use of the TAS defense, the differences between the suicidal and nonsuicidal groups were more significant than the differences between the Pre- and Postconformist (being highest for the suicidal groups), but for the nonsuicidal groups it was higher for the Conformist girls than for the Preconformists. Last, the use of reversal was higher for the Conformist nonsuicidal girls, but not the Conformist suicidal girls, for whom it was almost as low as for the Preconformist nonsuicidal girls.

This study, while pointing at other factors (suicide ideation, in this case) that might influence defense use, nevertheless confirmed the other findings that reported the significance of differences in defense use as a function of ego development level (particularly in transition from Preconformist to Conformist ego development stages). As in the Noam et al. (1991) study, the use of principalization and reversal was higher for the Conformist than for the Preconformist adolescents, and the use of TAO and projection was higher for the Preconformist than for the Conformist adolescents. Amato (1991) explored the relationship between the level of ego development, defense mechanisms, and psychological separation during adolescence in a sample of normal 11th and 12th graders in a suburban Connecticut town. As in other

studies, the use of principalization was positively related to ego development (this association was stronger for males), and the use of TAO was negatively related to ego development.

In Noam's (1984) study, ego development was examined in relation to 14 defenses (classified in four defense factors based on Valliant's (1971, 1993) hierarchy of defenses, from the least to most mature). The results show that the action-oriented and projective defenses are negatively correlated with ego and moral development, and the more delaying and cognitively complex defenses, such as suppression, altruism, and intellectualization, increase as ego development increases.

All these studies were conducted with adolescent populations. A complex study that drew our attention to several problems in this area is Cramer's (1999) that used a sample of 98 young adults. She used a completely different defense mechanism system that only distinguished among three defenses (denial, projection, and identification), and thus her findings cannot be generalized with those cited earlier. However, she makes several points that appear to be extremely important. First, her sample was singularly representative and included subjects at every ego development stage, from Impulsive to Autonomous. All three defense mechanisms in the study were found to have curvilinear relationships with ego development. This fits the similar pattern of the relationship between ego development and other mental health measurements, implying that curvilinearity in ego development is related to mental health.

Another important characteristic of this study is that it considered IQ measurement and age as covariates of ego development and employed multivariate statistical tools. Particularly, IQ seemed to play a mediating role in the use of defense mechanisms (p. 756).

Summary and Conclusions

Every study that explored the relationship between ego development and the use of defense mechanisms employing the DMI found that the incidence of TAS and projection is much higher at the lower, Preconformist stages of ego development than it is at the Conformist stage. The same tendency, only slightly weaker, was found for the TAS defense mechanism. This strong finding does not seem surprising if we take into consideration the nature of those defenses. All of them presuppose not a transformation, but a rerouting of aggressive tendencies, either "through attaching an external object . . . or directing aggressive thoughts and behaviors toward oneself . . . or attributing negative qualities to an object as a

justification of expression of aggression” (Noam et al., 1991, p. 318).

Principalization and reversal, on the other hand, were found to be used more at the Conformist ego development stages. These are intellectualizing defenses that deal with negative emotions with a kind of transformation that changes one’s view of conflict, either by “splitting of emotions and affect from the content of the conflict . . . or by responding neutrally or positively toward a frustrating object” (Noam et al., 1991, p. 318).

Thus, the findings on relationship between ego development and defense mechanisms are consistent with each other and the conceptual predictions that could be expected in the framework of Loevinger’s theory. On the other hand, most of the studies cited used adolescent samples (see Chiesa, 1980) and explored the use of defense in the transition from the Preconformist to the Conformist ego development levels. The higher levels of ego development were left out of the picture. This is a problem that needs to be explored.

Our overall conclusion is that defense mechanisms, or more generally coping and adaptational scales, might be very important bridging constructs between ego development and symptomatology because they share with ego development an aspect of frame of reality/meaning. They also capture distortions and misconceptions, which have been viewed by many clinical traditions (e.g., psychoanalysis, cognitive-behavior psychology) as tied to psychopathology and symptomatology.

POSITIVE MENTAL HEALTH

In this section, we look at another end of the mental health spectrum and present evidence that suggests an answer to the question: Are people with high ego development more likely to have better positive mental health? We present research evidence on this topic, organized in accordance with the views the authors hold on the nature of positive mental health.

Positive Mental Health as a Single Variable, Similar to the Sense of Subjective Well-Being or Life Satisfaction

The hypothesis that people with higher levels of ego development are more satisfied with their lives was proposed as early as 1978 by Alker and Gawin. Using a large heterogeneous sample of religiously active adults ages 18 to 80, they conducted a correlational analysis of two variables: psy-

chological well-being and religious maturity based on Maslow’s theoretical model and measured by the Religious Orientation Scale (Allport & Ross, 1967). They found not only that more mature people were happier, but that they understood the very meaning of happiness differently from less mature individuals.

The research evidence obtained using Loevinger’s measurement of ego development as maturity does not support this claim. Young (1998) considered positive mental health as synonymous with maturity and measured it with two instruments: the Index of Adult Adjustment (Picano, 1984) and the Psychological Well-Being Scale (Ryf, 1996). A distinct characteristic of the sample was that the participants of her study were White middle-class women who scored higher than the general population on ego development; the Self-Aware stage, the modal stage for the general population, was the lowest stage observed in the sample. The researcher found no significant relationship between ego development and maturity. Among significant findings is that women who are high on both maturity and ego development were found more likely to have raised children than women low on both, or high on ego development but low on maturity. Thus, maturity was found to be a more salient factor for predicting successful completion of life’s essential tasks. A similar pattern was observed with income: Women high on both ego development and maturity were found to have higher incomes than women low on both or high on ego development only. The conclusion that one can draw from this study is that for middle-aged, middle-class women, reaching high, Postconformist stages of ego development does not mean having better adjustment or life satisfaction.

McCrae and Costa (1980) failed to find any association between the level of ego development and positive affect from the Affect Balance Scales (Bradburn, 1969) for a sample of 240 men from the Normative Aging Project. A secondary confirmation of the finding that there is no relationship between ego development and the feeling of life satisfaction comes from Diamond’s (1996) study. Her main goal was to explore the construct of integrative complexity (IC; Suedfeld & Tetlock, 1977) in its relationship with other variables, including ego development. In Diamond’s model, IC is a variable tapping into “structural complexity with which a person narrates and interprets significant autobiographical events” (Diamond, 1997, p. 1). This study explores the relationship between integrative complexity, ego development, and the feeling of life satisfaction as measured by the Satisfaction with Life Survey (Diener, Emmons, Larsen, & Griffin, 1985) and Overall Happiness with Life Scale (Fordyce, 1977). Only the correlations be-

tween integrative complexity and life satisfaction, and integrative complexity and ego development were obtained. Both associations were positive and significant, which confirmed the findings obtained by other researchers (Pratt, Diessner, Hunsberger, & Panser, 1991; Slugoski, Marcia, & Koopman, 1984). This is also intuitively understandable, as by definition, integrative complexity and ego development are clearly related constructs, both referring to the complexity of the person's understanding of self and the world around one. Diamond found no significant relationship between integrative complexity and either of the two life satisfaction measurements.

Positive Mental Health as a Compound Construct

Another approach to positive mental health is to consider it as a sum of two aspects: satisfaction with life and satisfaction with oneself. This view goes back to Erikson's (1968, p. 165) writings about identity, which, in its optimal form, should be equal to "a sense of psychological well-being, . . . of being at home in one's body."

King, Scollon, Ramsey, and Williams (2000) explored the relationship between ego development and subjective well-being in parents of children with Down syndrome. Multiple measurements, including WUSCT, the Satisfaction with Life Scale (Diener et al., 1985), the Rosenberg Self-Esteem Scale (Rosenberg, 1979), and narrative account assignments were administered over two time points with an interval of 2 years. Forty-two out of 87 participated in the follow-up study. In line with the other studies, the researchers found no relationship between ego development and life satisfaction on either time point. What did display a significant positive correlation with ego development was the self-esteem measurement. Also, when the narrative accounts were analyzed by content, the variable called "accommodation" (a feeling of being changed, accommodated to life as a result of traumatic events) positively and significantly correlated with ego development.

Several conclusions can be drawn from this study. First, it is likely that ego development does not display an interaction with a person's subjective feeling of satisfaction with life. On the other hand, ego development was found to correlate positively with self-esteem, which the authors took as a component of adjustment. Thus, if successful life adjustment presupposes two components, satisfaction with life and satisfaction with oneself, the former component is independent of ego development (in other words, people at lower levels have equally high chances to be as happy as people at higher levels of ego development), and the latter correlates posi-

tively with ego development (people at higher ego development levels are more satisfied with themselves).

A positive relationship between ego development and self-esteem was found in a number of other studies (e.g., Raygan, 1991; Rogers, 1980; Schaffer, 1983; Schoeberlein, 1997). However, we do not know as of yet the directionality of these relationships: Is it higher self-esteem that supports ego development, or is it ego development that increases the likelihood of high self-esteem?

A similar model of positive mental health as a composite of two or more dimensions was employed in Helson and Srivastava's (2001) study. It was based on Ryff's (1989) model of positive mental health. Ryff proposed two components of positive mental health: personal growth and environmental mastery. Just as in the earlier model, Ryff distinguishes between the component that taps into the person's relationship with the world and the person's relationship with self. Based on the two dimensions, Ryff proposed a positive mental health typology. She divided the population into the following:

- Achievers, high on both environmental mastery and personal growth.
- Seekers, high on personal growth only.
- Conservers, high on environmental mastery only.
- Depleted, low on both: people with a lack of positive mental health.

Helson and Srivastava (2001) employed Ryff's model and, after dividing the sample of 111 women into the four positive mental health types, explored the relationship between positive mental health and a list of related variables, including generativity, social competence, wisdom, ego development, and life satisfaction. The results they obtained are similar to the results of the other studies cited in this review, with several additions.

The Seekers group (high on personal growth) were highest on ego development. This group was also highest on wisdom, thus supporting the relationship between these two constructs. According to Ryff's classification, this is the group concerned with personal growth, but not environmental mastery. This explains and supports the relationship between ego development and self-esteem. People who are concerned about their personal growth and who, most probably, channel their lives so that they can hone their personal growth, are more satisfied with themselves. The same people were relatively low on life satisfaction and conventional social adjustment measured by the Index of Adult Adjustment (Picano, 1984), which, again, is in line with the other findings. (Another approach to adjustment

emerges from treatment results or mental health outcomes after counseling.) This topic is dealt with, for example, in Dill and Noam (1990), Loevinger (1980), Shainbart (1995), and Van Ormer (2001).

Ross (2001) arrived at results similar to these, with one important difference. She found that for the people who experienced the death of a parent as adolescents, the ego development levels were higher than for matched controls. Also, the personal congruence was higher (the discrepancy between the real and the ideal self, which is closely related to self-esteem), and the depression levels were no different than for the control group. The model that emerges here is causal: It follows that traumatic events, pain, or conflict (which, of course, would lead to lower levels of happiness or life satisfaction) might in fact be the source of personal growth resulting in high ego development and high personal congruence (self-esteem).

This line of reasoning can be traced back to Piaget, who proposed disequilibrium as a source of development. Far from being conclusive (e.g., other studies show a lack of relationship between happiness and ego development, not a negative correlation), this model nevertheless appeals to investigators. The most suitable research design here seems to be a longitudinal study that would explore the relationship between life events, levels of happiness (life satisfaction), and ego development with the goal of finding their causal path of interdependence over time.

Positive Mental Health as Different for Ego Level Groups

Yet another approach, probably the most advanced one, assumes that there is no point in attempts to measure the association between the feeling of life satisfaction and ego development, because for people at varying ego development levels, the very experience and understanding of happiness will be quite different.

Labouvie-Vief, Hakim-Larson, deVoe, and Schoeberlein (1989) distinguished four levels of emotional understanding: presystemic, intrasystemic, intersystemic, and integrated.

At the lowest (presystemic) level, emotions were described in terms of egocentric standards and impulsive thoughts and actions, and the feeling of life satisfaction was equal to personal comfort. At the next (intrasystemic) level, emotions were described in conventional terms, and the feeling of happiness was a projection of what might be experienced as a positive emotional situation by the people of one's group. At the intersystemic level, inner sensations were recognized; it was only at this level that the true personal feeling of satisfaction appeared and was experienced and acknowledged. At the integrated level, the dual nature

of emotions as bodily and mental phenomena was recognized; thus, happiness could be experienced as harmony with the environment and other people's feelings.

The results of this study showed clearly "a developmental trend in these levels as a function of age" (Labouvie-Vief et al., 1989, p. 279). The emotional level scale correlated at .70 with ego development and with verbal ability for the subsample of 28 adults of different ages. Thus, the researchers showed that for people at different emotional (and thus ego) levels, the experience, understanding, and control of emotions were qualitatively different.

Summary and Conclusions

Even though the evidence of the relationship of ego development and positive mental health is not abundant, a few tendencies can be distinguished, and some conclusions seem well supported.

First, if we consider mental health as a unidimensional construct equal to the feeling of personal well-being and life satisfaction, most studies show no significant relationship between it and ego development. If we distinguish between two aspects of positive mental health, one tapping into a person's relationship with self and another focusing on one's relationship with the environment, a different schema emerges. One's feeling of satisfaction with the environment seems quite unrelated to one's level of ego development, yet one's satisfaction with oneself is definitely higher for people at the higher ego development stages. Thus, at least one component of positive mental health seems to correlate positively and significantly with ego development. This is the finding obtained in the majority of studies concerned with the question.

Another position holds the view that the very meaning and experience of happiness and satisfaction is so different for people at higher ego development levels that it seems meaningless to measure those different sensations with the same instrument, be it a measurement of emotional well-being or of life satisfaction. Definitely, more research in this area would shed more light on the problem, which might offer some answers to the age-old human questions about the meaning and ultimate importance of happiness.

FAMILY CONTEXTS IN RELATIONSHIP TO ADOLESCENT EGO DEVELOPMENT AND MENTAL HEALTH

One area where the topic of mental health in its relationship with ego development becomes extremely important from the theoretical, methodological, and practical points

of view is the area of family contexts of adolescent development. The issues of family, attachment, and the interplay of personal and contextual factors in this crucial period of human development are directly connected to psychosocial risks, symptoms, and dysfunction. Also, many studies conducted on the topic are more complex than those that involve only ego development and one particular disorder. Thus, the complex models emerging in this area are representative of the next stage of research, where more complex theoretical and empirical models are being tested.

Another contemporary trend that emerges in most advanced research is a view that a person as much shapes his or her contexts as the context influences the person. In application to the adolescent development field, we take it for granted that adolescents shape their parents and the family atmosphere as much as the family shapes them (Grotevant, 1998; Hauser, 1991). Thus, even though it is customary to use such words as "family influence" and "adolescent outcomes," we will be talking about associations between variables, such as parenting style and adolescent decision-making strategies, in terms of associations, without implying causality, in every instance except for one longitudinal study.

To make sense of the abundant literature on the topic, we find it useful to classify the constructs being studied into three categories. First, we explore the research that studies parenting styles, family warmth, parents' ego development levels, and family history scales in their relationship to ego development (see Guerra, 1991, for parental alcoholism on ego development in offspring). Second, we review studies that focus on characteristics of the adolescents, those that can usually be divided into positive attributes, such as self-esteem, educational attainment, productive decision making, and ego resiliency, and negative dimensions, such as risk behaviors and aggressiveness. In the third class we put four constructs: ego development, mental health status, attachment, and gender. The integrated model that the evidence seems to be implying is that ego development, attachment, and mental health serve as mediators between the family variables and adolescent variables, and gender might be moderating the associations. Thus, even though these complex, integrated models are employed in only some studies and not in others, they are beacons for future research in this area, the next step that is being taken by an increasing number of researchers.

Relationships between Adolescent Variables, Ego Development, and Mental Health

Win (2001) studied the relationship between attachment (as measured by the Inventory of Parent and Peer Attach-

ment; Armsden & Greenberg, 1987), ego development, and utilization of social support for unusually young college students (15 to 17 years). The results show that the ability of those adolescents to utilize social support available for them on campus, such as peers and counselors (which, in turn, translated into the overall college adjustment), was significantly related to both attachment (in that system, not an attachment typology, but a total attachment score is used, with the lowest score representing the weakest and the highest score the strongest attachment) and ego development level. Particularly, student satisfaction with companionship, satisfaction with emotional support, and overall satisfaction with support were higher for those with a higher overall attachment score. Level of ego development was also found to be associated with satisfaction with companionship, with the Postconformist group being more satisfied than the Conformist group and the Preconformist group being the least satisfied of all. Gender was not significantly related to the social support variables.

The relationship between attachment and ego development was tested using the Duncan test of group means and found significantly different (significance at $p < .05$) for the three ego level groups: the lowest for the Preconformists, average for the Conformists, and the highest for the Postconformist adolescents.

One methodological note is due before we proceed any further with this review. As attachment and ego development were found to be related (in Win's 2001 study, as in other studies to be cited), then to achieve accuracy in the conclusions, the partial correlations between the adolescent variables, ego development, and attachment need to be calculated. In doing so, several schemas need to be tested. Ego development and attachment might be considered joint predictors for the outcome variables, or they can mediate each other's influences. Statistically, a variable is a joint predictor if it adds to the proportion of the explained variance, and a mediator if it lessens an increment of an independent variable whose influence it mediates (Baron & Kenny, 1986). The best suggestion is to test all four schemas (each of the variables as a joint predictor and as a mediator) in any research concerning ego development and adolescent outcomes.

In Win's (2001) study, attachment score remained a significant predictor of the satisfaction with social support even when controlling for the level of ego development.

Laird (2000) found ego development to be related to the decision-making patterns in pregnant adolescent girls age 15 to 19. In that study, "the naturalistic patterns of decision-making employed by the young women during their interaction in group sessions and through their conversations about pregnancy resolution decisions were examined"

(p. xiii). These qualitative data were then compared with the six subjects' ego development levels. No other variables were used in this study.

Schoeberlein (1997) found a significant positive association between ego development and self-esteem in a mixed sample of 99 homeless and 99 housed adolescents age 12 to 17. Ego development was tested as a predictor for self-esteem as an outcome variable. In the multiple regression analysis, age and IQ were tested as covariates used to test the unique increment in adolescent self-esteem, explained by ego development only. It was still high: r .20 in bivariate regression, .19 controlling for age, and .22 controlling for both age and IQ (all significances at $p < .01$ level). Although gender was found to be related to ego development in the manner found elsewhere (females having on average higher ego development than males), the moderating role of gender on the ego development-self-esteem relationship was not obtained.

Relationships between Family Variables and Ego Development/Mental Health/Attachment

Allen and colleagues (Allen, Hauser, Bell, & O'Connor, 1994) examined adolescents' level of ego and autonomy-relatedness in their relationships with fathers and mothers as measured by the Autonomy and Relatedness Coding System (Allen, Hauser, Bornam, & Worrell, 1991). In this study, ego development was considered a dependent variable. Not surprisingly, behaviors exhibiting autonomy/relatedness were positively related to ego development. Behaviors exhibiting only autonomy but not relatedness or only relatedness but not autonomy were negatively related to adolescents' ego development. When mental health status (hospitalization history) was taken into account, the relationship between autonomy/relatedness and ego development remained significant. No interaction effects were found for gender. The importance of this study lies in stressing the significance of the balance between two dimensions of family interactions—autonomy and relatedness—and in using gender and mental health history as moderating variables, even though the effect of gender was not found to be significant.

Hiraga (1996) studied family processes and ego development in a sample of 42 adolescent girls. Ego development was predicted by maternal warmth, behavioral control, psychological control, and cognitive enabling. Neither the role of father nor other mediating variables such as attachment were taken into consideration in this study. Thus, for adolescent girls, a combination of maternal warmth and con-

trol was found to be the best predictor for the daughters' ego development.

The importance of Hiraga's (1996) study lies in the fact that she concentrated on the minority family processes; Luthar and Quinlan (1993) added cross-cultural aspects to the topic of family processes. They explored the relationships between parental characteristics (Care and Protect scales from the Parental Bonding Instrument; Parker, Tupling, & Brown, 1979), ego development, depressive tendencies as measured by the Depressive Experience Questionnaire (Blatt, D'Afflitti, & Quinlan, 1976) for the two samples: female college students in the United States and their counterparts in India (these were older adolescents; the mean age was 19.6 for the Indian students and 21.0 for the American students). The results were slightly different for the two cultures. For the Indian students, ego development was found to be associated with both parents' Protection score (though the sufficient significance level has not been achieved); for American students, ego development was positively associated with the paternal Care score.

This study draws our attention to one more methodological consideration related to the problem of family and ego development. As the evidence cited in this review suggests, many mental health problems are related to ego development, and severity of disorder is always inversely related to it. Thus, when exploring the relationship between family variables and ego development, mental health variables should be taken into consideration. Mental health variables and ego development may be tested as joint predictors or as mediators.

In Luthar and Quinlan's (1993) study, only bivariate correlations among parenting variables, ego development, and depression subscales were obtained. Richards, Gitelson, Peterson, and Hurtig (1991) studied effects of a diverse group of parental variables (such as warmth, active involvement, rejection, hostile control) on the levels of ego development of 139 high school students ages 17 to 18. The researchers found that although ego development was associated with more encouraging, warmer mothering for boys, it related weakly to mothering for girls. The fathers' role was not found to be significant for their children's ego development, which contradicts the other studies cited.

Von der Lippe (2000) explored relationships between family interactions and daughters' level of ego development in a sample of 39 families led by fathers and mothers with adolescent daughters ages 16 to 19. The new and important feature of this study is that parents' level of ego development (for both mothers and fathers) was also included in the list of variables. The daughters' ego level was associated significantly with their father's but not

their mother's ego level, which confirms the importance of the opposite-sex parent for the adolescent's development. When daughters' age, parental SES, and parental ego development were controlled for in the hierarchical regression analysis, fathers' cognitive and affective enabling and mothers' affective enabling were significant contributors to the daughters' ego development. Another interesting finding of this study is that mothers' challenging behaviors and parental autonomy from responding in kind to their daughters' communications also predicted adolescents' level of ego development, thus supporting the idea proposed in other Von der Lippe works: that family conflict combined with a supportive atmosphere enhance adolescent levels of ego development, in spite of a commonsense view that a good family is a family without problems.

The issue of family conflict was further explored in another Von der Lippe study (Von der Lippe & Moller, 2000). In this study, adolescent level of ego development was used as a predictor for family characteristics of family communication and patterns of conflict negotiation. Thirty-nine late-adolescent females, age 16 to 19 (mean age 17.5), and their parents were studied. It was hypothesized that "the ego development of adolescent females would be positively related to the quality of the conflict negotiation in their families as it reflects the individuation of the [family] system" (p. 60). The hypothesis was confirmed. The results show that when the daughters achieve higher developmental levels, the family as a whole negotiate conflict in more productive ways, the ways that presuppose a balance of "autonomy and relatedness" (Allen et al., 1994) or, in Stierlin (1974), "individuated relationships."

In a similar study by Hauser, DiPlacido, Jacobson, Willett, and Cole (1993), several family coping strategies were found to be related to adolescents' level of ego development in 79 families with adolescent diabetic patients. Among these strategies were cognitive flexibility/perspective taking, experience of mastery, seeking information, direct expression of feelings, and awareness of helplessness. All these strategies were linked with more advanced levels of adaptation to the stress that adolescents' illness represented for the families. The coping strategy avoidance, expected to be linked to lower levels of adaptation, was inversely correlated with adolescents' level of ego development.

In another study by Hauser and colleagues (1984), relationships between family interactions measured by the Constraining and Enabling Coding System, newly developed by the same researchers and later used by many others interested in family and adolescent research, and

parental and adolescents' ego development levels and adolescent mental health, were explored. As in the earlier studies, adolescent ego development was treated as an independent variable and family interactions as dependent variables. After controlling for adolescents' age and mental health status, adolescents' ego development level was found to be positively associated with adolescent enabling behaviors (problem solving, empathy) and negatively correlated with constraining behaviors (devaluing, withholding). Parental behaviors were associated with both parents' and adolescents' ego levels, with enabling behaviors related to higher ego levels and constraining behaviors related to lower ego levels.

Relationships among Ego Development, Mental Health, Attachment, and Gender

There are several studies that explore interrelationships among the four variables that the emerging model implies are the mediators between family and adolescent variables. These studies are extremely important as they provide evidence that the four mediating variables are interrelated and, thus, for the accuracy of conclusions, should be taken into consideration together.

McLauchlin (1997) explored the relationship among three variables: mental health (severity of personality pathology, measured by the MCMI-III), ego development, and attachment status (secure vs. insecure, measured by the Adult Attachment Questionnaire; Feeney, Noller, & Hanrahan, 1994) in a large sample ($N = 249$) of older adolescents—undergraduate students in an urban university. For this sample, where the distribution of the participants across ego development stages was similar to those characteristic of normal adult populations (the majority scoring at the Self-Aware ego stage, with a substantial proportion at the Conscientious stage, and only about 5% scoring below the Conformist stage), ego development was found to be positively associated with secure attachment chi-square of 5.42, significance $p < .02$ for two attachment groups (securely vs. insecurely attached) and two ego development groups (a small fraction of Preconformists plus Conformists in one group and Postconformists in another group). Ego development was inversely associated with severity of personality pathology (Pearson correlation of $-.14$, $p < .05$) and a total personality score for each participant who demonstrated a clearly defined high point and correlation of $-.19$ ($p < .01$) between ego development and the sum of all 14 personality scores. The relationship between attachment style and personality pathology was found to be more complex.

Summed personality scores were computed for each attachment category. Securely attached individuals had the lowest score (and thus the lowest pathology) and preoccupied individuals had the highest score, with dismissing and fearful types falling in between. When particular personality types were considered, dismissing individuals were more likely to have schizoid, avoidant, narcissistic, or compulsive personalities. Participants classified in the preoccupied attachment category were more likely to have borderline, depressive, self-defeating, and histrionic personalities. Participants classified in the fearful attachment category were more likely to have paranoid, antisocial, and aggressive-sadistic personalities. Securely attached individuals were most often classified in the “moving toward others” personality cluster (e.g., depressive, self-defeating, and histrionic, excluding borderline).

England's (1997) study provides more evidence in support of the relationship between attachment category and ego development level. In her study, two groups were compared on both attachment styles measured by Hazan and Shaver's (1987) Measure of Attachment Styles and level of ego development: a group of 99 adult incest offenders and a matched control group. The incest group was significantly lower on ego development and also included more insecurely attached participants than the control group, which implies a positive association between lower levels of ego development and insecure attachment. Yet, because the participants in the study were adults, not adolescents, it is only of secondary significance to the topic of this section.

Studies That Consider Ego Development and Attachment as Mediating Variables between Adolescent and Family Variables

In the following studies, the variables from all three clusters (family, adolescent, and mediating) were explored in their relationship with one another. In many instances, the mediating roles of ego development, mental health, attachment category, and gender were acknowledged and taken into consideration in the statistical analyses.

Du Mont (1998) studied the effects of early pubertal development, family warmth, and ego development on risk behaviors (early coital debut, cigarette smoking, and drug use) in adolescent girls. She used two adolescent variables (early pubertal development and risk behaviors, the former as independent variable and the latter as dependent variable), family variable, and ego development as mediating variable. As predicted, family warmth reduced the risk behaviors, not directly, but through ego development and through pubertal development (family warmth was nega-

tively related to pubertal development, which was positively associated with risk behaviors). Moreover, two adolescent variables—early pubertal development and risk behaviors—were related both directly and through ego development as mediating influences of early pubertal development on risk behaviors. Thus, ego development was found to be able to negate a part of the negative influence of the early pubertal development on risk behaviors (early pubertal development related positively to both risk behaviors and ego development, and ego development reduced the probability of risk behaviors).

In the following two studies, the model we described in the beginning of this section (e.g., ego development, gender, and mental health as mediating relationships between family variables and adolescent variables) was employed. Isberg et al. (1989) explored the influence of family interactions as measured by the Constraining and Enabling Coding System (Hauser et al., 1984, 1987) on adolescents' self-esteem as measured by the Coopersmith Self-Esteem Inventory (Coopersmith, 1967). Mental health status (psychiatric patients, diabetic patients, and healthy high school students were subsamples), gender, and ego development were mediating variables. Among these, health status was the strongest mediator; the significance of age, gender, and parental SES was somewhat lower. Together, the effects of parental accepting or devaluing behaviors were strongest for psychiatrically ill boys. After the health factors were controlled for, all parental influences were still significant for boys, but not for girls, for whom only fathers' acceptance correlated positively with school self-esteem. The importance of this study lies in the fact that moderating effects of ego development were studied here: Parental behaviors correlated significantly with self-esteem in Preconformist but not in Conformist and Postconformist adolescents. This leads us to the conclusion that family processes and their relationship with various adolescent variables depend on adolescents' ego development levels and are different for Preconformist and Conformist adolescents.

Best and Hauser's (1997) study employed a longitudinal design with two time points 11 years apart. Parenting behaviors measured by the Constraining and Enabling Coding System (Hauser et al., 1992) and the Autonomy and Relatedness Coding System (Allen, Hauser, Borman, & Worell, 1991) were tested as predictors of the children's educational attainment and ego resiliency 11 years later. Adolescent ego development and mental health status were used as mediating variables. Even when controlling variables were accounted for, parental encouragement of adolescent autonomy and relatedness was related positively to the young

adults' educational attainment. Addition of the ego development significantly improved prediction of the educational attainment 11 years later, accounting for an additional 11% of the variance. Together, ego development and parenting behaviors accounted for 27% of the variance in the young adults' educational attainment. Also, ego development was found to mediate the relationship between parental behaviors and both educational attainment and ego strength in young adults.

This study is also important in that it draws researchers' attention to the statistical difference between using ego development as a joint predictor with a significant increment in multiple regression analyses and using ego development as a mediating variable. In this section, we talk about ego development as a mediator between family and adolescent variables for several reasons. First, it has been confirmed by Best and Hauser's (1997) study. Second, it is theoretically sound to expect the mediating effect if ego development correlates with both parenting and adolescent variables, and several studies cited in this review uniformly confirm that it does. Yet, only some, but not all, studies use ego development as a mediator; many only explore its additional contribution to the magnitude of prediction (see also Chilton, 2001). As the joint evidence brought together here suggests, ego development most probably plays both roles.

Summary

This subsection had a twofold goal: first, to describe the integrated theoretical model that emerges in the recent studies of the mutual influences of adolescents and their families (including the methodological nuances pertinent to the model), and second, to summarize the tentative conclusions that the cited studies seem to suggest.

In the model, four interrelated factors were found to be related to both family and adolescent characteristics and to mediate their mutual influences: mental health status, ego development, attachment, and gender. Thus, we stressed the importance of using these factors in family/adolescent studies, both as mediators and as joint contributors to the predicted variances.

Taken together, the studies we cited suggest that family warmth and relatedness (see also Bartholomew & Horowitz, 1991, for relationships to attachment styles) are as important to adolescent development as challenging and autonomy-encouraging behaviors in parents, but only when they occur in a warm, supportive context. The role of adolescent ego development was found to be important for nearly every aspect of adaptational family functioning, from productive coping strategies and productive ways of

conflict negotiation, to being able to negate destructive influences of risk variables, such as early pubertal development in girls.

SUMMARY AND FUTURE DIRECTIONS

The importance of using the cognitive-developmental personality paradigm in clinical research and practice has become evident as increasing numbers of studies have been conducted at the intersection between Loevinger's theory of ego development and mental health.

In an attempt to generalize the multitude of findings brought together in this review, we need to make a distinction between general conclusions on the nature of the relationship between ego development and psychopathology and more specific findings concerning relationships between ego development and various disorder groups.

Generally, the majority of clinical samples reflect moderate to significant delays in ego development. Another general conclusion supported by the evidence is that for most disorders, symptom expression is different at different ego development stages.

Among specific disorders, personality disorders (especially Borderline Personality Disorder, Conduct Disorder, and delinquency) and substance-related disorders were found to display the strongest relationships with ego development. The former is not surprising, as Loevinger's theory of ego development is a cognitive-developmental personality theory, and thus it is only natural to expect that a delay in personality development would be related to personality disorders. The latter should be expected based on Loevinger's description of one domain of ego, impulse control, an aspect of substance abuse disorders. One specific finding in this area, a possible relationship of substance abuse, ego development, relational deficiency, and depressive tendencies, is a prominent line of research that needs more exploration.

Another emerging tendency that needs further exploration is a nonlinear relationship between ego development and some disorders (such as mood disorders, anxiety, and such mental health-related emotions as guilt and shame). In particular, it has been found that Conformist stages of ego development might be where the social pressure to fit in and measure up to group norms is the highest and the risk of depressive and anxious problems is great. The use of curvilinear statistical tools seems advisable in the ego development research.

Another strong methodological tendency in this area is a movement to more complex models and multivariate

methods that account for mutual influences of many variables that allow one to build models. At the other end of the mental health spectrum, positive mental health in its relationship with ego development has not yet become a prominent area of research, yet, we chose to review the studies that have been conducted in this direction as concentration of research efforts on maladaptation alone cannot yield a comprehensive explanation of how ego development interacts with adjustment processes during the course of life. Among the life course periods, adolescence seems to be the time when the developmental stage rather than age or phase is extremely important. Too often in developmental psychopathology research there is a singular focus on chronological age rather than developmental complexity and maturity. Future research will have to systematically take this relationship between chronological age, developmental stage, and psychopathology into consideration.

Methodologically, the use of more complex multivariate models and curvilinear tools is becoming more prevalent and will need to accelerate in this active area of study. Also, more studies with specific psychopathologies, such as personality disorders, anxiety disorders, and eating disorders, are clearly needed to complete the picture of this line of developmental psychopathology research. An intriguing and practically important topic of treatment implication and long-term outcomes in psychopathology has not received sufficient attention. Also, along the line of building more complex models, an integration of other developmental measures into the research on ego development and psychopathology might enrich our understanding of the developmental processes and be useful in assessment and clinical practice.

Taken together, the studies reviewed in this chapter show important patterns that will be significant in shaping a field of study and in developing lines of research that can make an important contribution to how we think about disorders from a developmental point of view. These findings also provide a direction for how we can begin to tailor interventions to augment existing ways of treating mental illness and mental health problems.

REFERENCES	841

Concepts related to autonomy figure prominently in organismic and dynamic theories of development and psychopathology. Classical developmental theories, for example, have considered the movement toward greater autonomy and self-initiation to be a hallmark of healthy development (e.g., Hartmann, 1947/1964; Jahoda, 1958; Loevinger, 1976; Piaget, 1981; Werner, 1948). An important theme in the literature on parenting and social development also concerns the promotion of autonomy and self-regulation, as well as the negative impact of controlling parenting environments that thwart autonomy (e.g., Baumrind, 1971; Grusec & Goodnow, 1994). In a similar vein, the literature on psychopathology includes frequent mention of autonomy disturbances (e.g., Bruch, 1973; Shapiro, 1965; Winnicott,

1960/1965), and the obstruction of children's autonomy has been implicated in the onset of many psychopathologies (e.g., McCullough & Maltzberger, 1995; A. Miller, 1981).

At the same time, the concept of autonomy is one of the most controversial theoretical constructs in the literatures of development, socialization, and well-being (Deci & Ryan, 2000; Ryan & Deci, 2003). Some theorists define autonomy as freedom from all environmental influences, a nonsensical concept (Bandura, 1989), whereas others view it as a critically important developmental issue (Zimmer-Gembeck & Collins, 2003). Some view autonomy in terms of breaking emotional bonds with caregivers and becoming "individuated" (e.g., Blos, 1979; L. Steinberg & Silverberg, 1986); they are opposed by theorists

who see autonomy and connectedness with significant others not only as compatible but as inherently interdependent (Ryan & Lynch, 1989). Some writers view autonomy as a Western concept, pertinent only to societies that place a high value on individualism and self-direction (Markus, Kitayama, & Heiman, 1996; Oishi, 2000), and others postulate that autonomy is a deeply evolved (Waller, 1998) and therefore universally significant human capacity (Chirkov, Ryan, Kim, & Kaplan, 2003; Kagitçibasi, 1996). Still others have construed autonomy as a masculine attribute that does not address the significance of relatedness and connectedness that is central to women's development (e.g., Gilligan, 1982; Jordon, 1991), but they are opposed by a growing number of feminist and relational perspectives (e.g., Friedman, 2003; Lerner, 1988; Mackenzie & Stoljar, 2000) and by empirical evidence (Deci, La Guardia, Moller, Scheiner, & Ryan, 2004; Ryan & Deci, 2003) supporting the importance of autonomy for women as well as for men.

What such controversies point to is not only the potential significance of autonomy as a psychological construct, but also the need for conceptual clarifications that can address these debates as well as connect with the empirical evidence. Only through such means do semantically based clashes become resolved, conflicting hypotheses highlighted, and practical theory advanced. Thus, although the concept of autonomy is invoked in many theories, relatively few writers have explicated its specific meaning, its developmental, experiential, motivational, and cultural facets, its role in psychopathology and mental health, and the influences of social contexts on which it is dependent.

In this chapter, in keeping with the spirit of the field of developmental psychopathology, our interest is in examining both the developmental underpinnings of healthy autonomy and the processes involved in its disruption and manifestation as pathology (Cicchetti & Tucker, 1994). It is in critically examining this interface between normal and impaired development that the nature of autonomy is most fully revealed. We set forth a definition of autonomy that is informed by both philosophical and clinical analyses and that differentiates autonomy from closely related constructs such as free will, independence, individualism, and detachment. We then explore how autonomy is intertwined with the developmental processes of intrinsic motivation, internalization, attachment, and emotional integration, paying particular attention to how conditions in the social context either support the motivational and emotional bases of normal development or, alternatively, undermine these bases, leading to psychopathology. Fi-

nally, we discuss the experience and dynamics of autonomy with regard to varied psychological disorders, which we view as both outcomes of nonoptimal developmental antecedents and risk factors for continuing difficulties in self-regulation.

AUTONOMY: WHAT IT IS

Etymologically, the term autonomy refers to "self-rule," and indeed we apply the term to actions that are initiated and regulated by the *self*. Autonomous behaviors are those that a person willingly endorses. The opposite of autonomy as we employ the term is heteronomy, which is rule by forces that are experienced as alien to the self. When persons act autonomously, they feel "wholehearted," "together," and "ownership of their actions," all common expressions that convey the characteristic sense of integrity and volition essential to autonomy. Moreover, autonomous behaviors are experienced as fully self-endorsed because they are informed by and reflective of abiding needs and values, and they fit the actual circumstances to the best of the person's knowledge. In this regard, autonomy is therefore often thought of as behavioral regulation that is reflective (Dworkin, 1988; Frankfurt, 1971), mindful (Brown & Ryan, 2003), and integrative (Friedman, 2003; Ryan, 1993; Shapiro, 1981).

Although this definition of autonomy is fundamentally phenomenological, it is also clear that autonomous regulation has a functional side: When acting autonomously, the organism is undivided and fully functioning in the direction of its endorsed aims or goals. As we shall see, this functional quality is manifest in differential outcomes obtained when people act from autonomy versus from compliance, controlling rewards, or coercion. When autonomous people act more persistently toward their aims, they also have a more positive experience and an enhanced sense of self in the process.

The concept of autonomy relates to the distinctions between self-regulation and self-control and between volition and intention. It is clear that whereas all organized actions entail intention, not all intentional behaviors are autonomous. Moreover, although autonomous behavior is directed, it has a quality of openness and flexibility, rather than the rigid doggedness of self-control. Finally, although some theorists have equated autonomy with independence, persons can often be volitionally dependent and/or autonomously connected with others in their aims. Thus, au-

tonomy concerns less whether or not one relies on or cares for others, and more on whether reliance or caring is self-endorsed (Ryan, La Guardia, Solky-Butzel, Chirkov, & Kim, 2005).

Although the concept of autonomy refers, therefore, to regulation by the self, it should be clear that autonomy is always a relative concept in that actions can be more or less characterized by autonomy. Moreover, because both the self and the social demands and tasks that beset it develop, autonomy has to be understood in a developmental perspective. This includes considering not only the changing capacities and experiences of individuals over the life course, but also the actions that they are called on to regulate in social contexts (Ryan, Deci, & Grolnick, 1995).

Autonomy is defined here in terms of its phenomenology; later, we discuss in more detail its functional attributes and correlates. However, it is basic to our view that autonomy is a quality of regulation, characterized by an open processing of possibilities and a matching of these with sensibilities, needs, and known constraints. Obviously, this high quality and depth of processing depends on quite complex neurocircuitry, whose topography differs from that of more controlled motivational processes (Ryan, Kuhl, & Deci, 1997). In general terms, autonomy depends on coordination between prefrontal cortical regions and subcortical striatal-thalamic areas that promote or inhibit motivation, as well as inputs from the hippocampus and amygdala that can provide contextual and affective information (e.g., Bradley, 2000; Chambers, Taylor, & Potenza, 2003). In psychological terms, executive functions must be both selective and fully “informed” by affective and memory-related processes to support autonomy. Interference or damage in the development or functioning of prefrontal areas and connections with limbic structures produces strong vulnerabilities to autonomy disturbances, especially insofar as these entail affective processing (e.g., Bechara, Tranel, Damasio, & Damasio, 1996).

Although the neuropsychology of autonomy is not a central focus of this chapter or of self-determination theory as a motivational theory, there are several points to highlight. First, as we understand more and more about the brain’s activity during motivated action, we believe that the differentiations we make on functional grounds between different types of motivation will be manifest in distinct patterns of activation in neurocircuitries. Second, it is clear that just as the integrity of the brain impacts the quality of psychological and behavioral regulation, reciprocally, the social contextual experiences with which we mainly concern ourselves herein shape and often entrain that underlying phys-

iology, a tenet central to developmental psychopathology (Cicchetti & Tucker, 1994; Panksepp, 1998). Finally, autonomy, which is often naïvely dismissed as a “ghost in the machine,” is anything but. It is instead a distinct way of regulating activity and experience. At the same time, we believe that even as we connect neurology with psychology, this does not in any way threaten to reduce psychology to biology. Instead, we will continue to find that the regnant causes of behavior remain largely at the cultural, social, and psychological levels of analysis, where much of the “casual” determination of human behavior will always lie (Ryan & Deci, 2004).

Having provided a preliminary definition of autonomy as we employ it, it is important to remember that not all authors who use the term are referring to the same thing (Hmel & Pincus, 2002; Ryan, 1993). In the following sections, we discuss various interpretations of the concept of autonomy that are compatible with our current usage. Then, to further clarify our definition, we contrast it with interpretations of the concept that are not compatible with ours.

Autonomy as Internal Perceived Locus of Causality

Numerous psychological theories, largely in philosophical (Mackenzie & Stoljar, 2000), psychodynamic (Shapiro, 1981), and humanistic (W. R. Miller & Rollnick, 2002) traditions, consider the concept of autonomy to be highly important, whether treated in terms of agency, congruence, self-regulation, authenticity, will, or operating from one’s “true self.” Different theories have used varied terminologies and have addressed somewhat different issues, yet a shared idea, which we term autonomy, is woven through these various conceptions. Because these theories have been based primarily on clinical practice and experiential discoveries and because the concept reflects a quality of regulation rather than a specific set of behaviors, the concept of autonomy has been slow in making inroads into empirical psychology.

Our own conceptualization of autonomy, which is one aspect of a more general theory of human motivation, basic needs, and development that we refer to as self-determination theory (SDT; see Deci & Ryan, 2000; Grolnick, 2002; Ryan & Deci, 2000c; Ryan & La Guardia, 1999), is itself empirically based. Although we draw from dynamic and humanistic conceptions, the empirical emphasis and approach of SDT has its foundations in the “commonsense language” of attributions proposed by Heider (1958) and extended by deCharms (1968). We use their formulations as a starting point for investigations

that have shed new light on issues judged important by many theorists—issues such as authenticity, internalization, volition, and the true self—and that relate such issues to normal versus psychopathological development and to clinical interventions.

Heider (1958) began this tradition with his work *The Psychology of Interpersonal Relations*. The book grew out of his early interests in the fields of phenomenology and Gestalt psychology (e.g., Spiegelberg, 1972). Heider's focus was on the "naïve" psychology that informs our social behavior: the sensibilities and attributions that determine our reactions. Among the concerns that he argued were most central to social experience is making sense of whether behaviors or the outcomes resulting from them are caused by intentional, purposive actions of self and others, or are products of impersonal causes. Specifically, actions and their effects were said by Heider to be *personally caused* to the extent that they were intended—as evidenced by signs of effort, goal directedness, and ability. In contrast, some behaviors or events are not intended, as these result from forces beyond an agent's control; these were said to be *impersonally caused*.

Subsequently, deCharms (1968) suggested that even some intentional behaviors (actions that involve effort and organization) may not embody a true sense of personal causation. He pointed out that many intentional behaviors might be enacted because the person wants to do them or enjoys them, and these certainly appear to represent personal causation. Yet, other goal-directed behaviors may be enacted only because of external pressures or rewards. These represent a more complex case with respect to the personal/impersonal distinction, because although intentional, they are experienced as compelled or heteronomously driven. To handle this issue, deCharms proposed a further distinction within the category of personal causation, namely, that between an *internal* versus an *external perceived locus of causality*. With internal perceived locus of causality, one feels oneself to be an "origin" of action, whereas with an external perceived locus of causality, one experiences oneself as a "pawn" of outside forces. Although both types of action fall within the category of personally caused (or intended) behaviors, only actions with a perceived internal locus of causality represent what we herein describe as autonomy.

Deci and Ryan (1980a, 1985b) elaborated and refined deCharms's distinction, applying theirs to an understanding of intrinsically and extrinsically motivated behaviors. Intrinsically motivated behaviors, which are done for their inherent satisfactions, invariantly have an internal per-

ceived locus of causality. Such actions are experienced as a spontaneous self-expression and are wholly volitional. In contrast, Deci and Ryan argued that extrinsically motivated (i.e., instrumental) behaviors can vary considerably in their relative autonomy. Some extrinsically motivated actions are clearly pressured or compelled by outside forces and thus have an external perceived locus of causality. Other extrinsically motivated actions, however, can have an internal perceived locus of causality, specifically when the individual sees the behavior as reflecting a personally endorsed and well-integrated goal. Indeed, the relative autonomy of extrinsically motivated action directly corresponds to the degree to which the regulation of such action has been internalized and integrated, a point that will receive considerable elaboration as we proceed.

Ryan and Connell (1989) pointed out that this conceptualization of perceived locus of causality shifts the boundary between internal and external from the *person* to the *self*. It is one's phenomenal core, here referred to as self, that is the most appropriate referent for distinguishing between an internal and an external perceived locus of causality. In other words, a behavior would be said to have an internal perceived locus of causality to the extent that one experiences it as expressive of one's true self, when one feels both authentic in and responsible for one's actions.

There is an important implication to the use of the self as the boundary referent, namely, that the proximal cause of an action could be a force within the person that is not integral to the self and thus would have an external perceived locus of causality. This is the case in introjection, for example, in which a person feels compelled to do something to avoid feelings of guilt or to gain a sense of esteem (e.g., Ryan, 1982; Ryan & Connell, 1989). Extending this, we suggest that some extrinsically motivated behaviors are controlled by *external regulations* (e.g., someone else controls you with rewards and punishments); some are controlled by *introjects* within the person but external to the self (e.g., feeling you have to do something to avoid guilt); and some are initiated by processes that have been *identified* with and/or *integrated* into the self (e.g., doing something because of a personally endorsed and well-assimilated value). Although these varied types of extrinsic regulation all involve intentionality and instrumentality, they differ substantially in the degree to which they involve autonomy, each falling at a different place along a gradient of perceived causality (Ryan & Connell, 1989).

Just as internally prompted actions may not be autonomous, events initiated from outside the individual do not necessarily engender heteronomy (Ryan, 1993; Ryan &

Deci, 2004). An authority, for example, may tell you to do something. Insofar as you agree with the order or personally endorse the legitimacy of the authority, your behavior of following the command may be quite volitional and would thus have an internal perceived locus of causality. Yet, when authorities make their power the salient reason for acting, or exercise that power arbitrarily or capriciously, this is likely to undermine feelings of autonomy. As we shall see, the manner in which adults exercise their guidance over children has a great deal of impact on both the children's sense of volition and their likelihood of internalizing the adults' values or guidance. Later, we look more closely at the developmental antecedents and dynamic character of these varied regulatory processes.

DeCharms (1968) portrayed *intrinsically motivated* behaviors as the prototype of an internal perceived locus of causality, and some of the experiential qualities associated with intrinsic motivation do represent a kind of template against which other forms of regulation can be compared. And, as we pointed out, well-integrated extrinsic motivations can be equally highly volitional and self-endorsed and thus approximate intrinsic motivation in terms of the internality of their perceived locus of causality. In either case, assessing a person's experience of an internal versus external locus of causality provides an empirical marker for the extent to which an action is autonomous. It will also relate empirically and theoretically to such constructs as authenticity, true versus false self, and volitional self-regulation.

Whether people are intrinsically or extrinsically motivated, they are engaged in intentional behavior. By contrast, the absence of intentionality represents an amotivational state. Thus, a person is motivated (and actions are personally caused) only to the extent that the person intends an action and follows the intention with an expenditure of effort. *Amotivation*, in contrast, most often refers to a relative lack of action, for example, when one feels hopeless and gives up behaving (Deci, 1980; Deci & Ryan, 1985b). The term amotivation also describes behavioral events the person emits without intention. A spasm, for example—although an action emanating from a body—is not mediated by intention and thus is amotivated and has an impersonal locus of causality. More interesting, however, from both phenomenological and clinical viewpoints, are behaviors such as a reflexive emotional “outburst” in which regulatory processes are overpowered by a sudden surge of energy. In Heider's terminology, these impulsive behaviors have an impersonal perceived locus of causality. In such a case, a person might, for example, say, “I don't know what came over me” or “I lost it,” conveying the sense of an impersonal cause and ab-

sence of control in regulating behaviors. Such behaviors are, of course, motivated in the sense of being energized and explicable. Nonetheless, we refer to them as amotivated to convey the extent to which they are experienced by the actor as nonintentional and outside of personal control.

Most empirically based theories of motivation and self-regulation contrast motivation with amotivation but treat the former as a unitary concept (e.g., Bandura, 1989; Seligman, 1991). Yet, a consideration of autonomy requires differentiating the concept of motivation. Specifically, we focus on the extent to which one's motivated actions are *autonomous* (i.e., have an internal perceived locus of causality and emanate from the self) versus *controlled* (i.e., have an external perceived locus of causality and are coerced or regulated by some inter- or intrapersonal force external to the self).

Despite the unfortunate similarity in terminology, an internal versus external perceived locus of causality is quite different from an internal versus external locus of control (Rotter, 1966). An *internal locus of control*, and the closely related concepts of perceived control (E. Skinner & Edge, 2002) and self-efficacy (Bandura, 1989), refer to the belief that one can attain desired outcomes through intentional actions. *External locus of control* refers to believing that one cannot control outcomes, instead believing either that there is no contingency between behavior and outcomes or that one lacks competence to enact the requisite behaviors successfully. Accordingly, one would expect to find intentional (i.e., motivated) behavior in cases of an internal locus of control, and a lack of intentionality (i.e., amotivation) in cases of an external locus of control. Indeed, the concept of an internal versus external locus of control parallels Heider's (1958) distinction between personal and impersonal causation.

An internal locus of control need not imply autonomy or an internal perceived locus of causality. For instance, a girl who learns to successfully hide her feelings and to outwardly comply with demands to avoid arousing her father's abuse might have both an internal locus of control (Rotter, 1966) and self-efficacy (Bandura, 1989) with respect to avoiding abuse. Yet, even though she has the competence to control this outcome, she would likely experience an external perceived locus of causality because she is forced to act in the specified ways. Indeed, someone with an internal locus of control or self-efficacy can as easily be a pawn as an origin (deCharms, 1981; Deci & Ryan, 1985b).

Because of the extent to which these various motivational terminologies overlap in both substance and source, we present a classification table for clarity (Table 20.1). As

TABLE 20.1 Various Theoretical Concepts as They Relate to Autonomous Regulation, Controlling Regulation, and Nonregulation

Types of Regulation	Locus of Control (Rotter, 1966)	Efficacy Theory (Bandura, 1977)	Helplessness Theory (Seligman, 1975)	Attribution Theory (Heider, 1958)	Personal Causation (deCharms, 1968)	Self-Determination Theory (Deci & Ryan, 1985b)
Autonomous regulation	^a	^a	^a	Personal causation	Intrinsic motivation; “origin”; internal PLOC	Intrinsic motivation; integrated extrinsic motivation; internal PLOC ^b
Controlled regulation	Internal locus of control	Self-efficacy	Perceived controllability	Personal causation	Extrinsic motivation; “pawn”; external PLOC	External and introjected extrinsic motivation; external PLOC
Nonregulation	External locus of control	Ineffectance	Helplessness	Impersonal causation	Impersonal causality	Amotivation; impersonal PLOC

^aThe autonomy-control differentiation (or a comparable one) is not made in these theories. All intentional actions would nonetheless be said to involve an internal locus of control, self-efficacy, and perceived controllability.

^bPLOC = Perceived locus of causality.

can be seen from this table, self-determination theory differentiates not only between motivated and amotivated acts, but also between motivated acts characterized by autonomy and those characterized by being controlled (i.e., by being a pawn to forces outside the self).

As stated earlier, the importance of this phenomenological and attributional approach to autonomy rests primarily on the fact that by applying the perceived locus of causality construct, we have been able to address issues concerning the development and experience of autonomy versus heteronomy with empirical strategies. Factors that affect the perceived locus of causality are, in fact, those that affect autonomy and self-regulation and thus are important to issues of self-development, as research to be reviewed will illustrate. However, before turning to that literature, we first connect the concepts of autonomy and perceived locus of causality with related clinical concepts.

Autonomy as True Self

Autonomous actions, when viewed phenomenologically, emanate from the *self*. Accordingly, not all actions, even intentional ones, that come from the person are characterized by autonomy. Rather, autonomy refers only to those actions that are either experienced as one's own or are well assimilated and self-endorsed. In clinical settings, it is clear that much of what people do is not experienced by them as self-endorsed, but instead is all too often experienced as false, alienated, compulsive, impulsive, or even dissociated. Our concept of autonomy, then, relates rather closely to what some writers have referred to as one's “real” (Horney, 1950) or “true” (Winnicott, 1960/1965) self.

The idea of true self conveys that individuals sometimes behave in ways that reveal their core spirit and convey a sense of integrity and personal endorsement, and at other times they behave in ways that do not express that inner core but instead are more superficial and less integrated. Unintegrated regulatory processes typically develop as an adaptation to being contingently valued and/or controlled and thus serve both to manipulate others and to defend or preserve oneself (A. Miller, 1981).

Winnicott (1960/1965) specifically distinguished between true self and false self by suggesting that when acting from the true self, people feel real and “in touch” with their core needs and emotions. True self embodies their creative nature, their ability to freely initiate, to be vital, to enjoy existence. It is also the basis of informed, “whole-hearted” behavior. In contrast, when acting from false self, people display “as-if” personalities that formed while they were attempting to gain approval in a nonaccepting social context (A. Miller, 1981). False self involves taking in aspects of the social context without truly accepting them as one's own. It conveys a splitting between one's outer presentation and one's deeper feelings and needs, a feature of many clinical presentations.

Whereas true self is the source of spontaneous perceptions, needs, and behaviors, false self reflects habitual perceiving and responding that a child adopts instrumentally, in accord with narcissistic needs. According to Winnicott (1949/1958), false self employs cognitive functions to know what is required of it—that is, to know what the situation demands—and in so doing, cognitive processes can gradually become separated from their affective and somatic grounding. In fact, Winnicott argued that living a

false self requires ongoing and excessive cognitive activity, to the neglect of feeling and open perception. We see here how the idea of autonomy as activity regulated by one's true self also has implications for the idea of psychological integration as coordination or synchrony among aspects of one's personality. To the extent that one acts from other than the true self, some fractionation and splitting of functioning will result.

Other writers in the psychoanalytic tradition have also discussed the concept of true or real self. Horney (1950) defined the real self in terms of an intrinsic potentiality, a tendency toward personal growth and fulfillment. She tied neurosis to alienation from the real self, which results in the loss of the vital energy that is available to the real self. Jung (1951/1959) described the self as an organismic endowment representing the "center" of personality and possessing the tendency toward integration. Although in Jung's theory, the self is largely unconscious and is manifest through dreams and symbols, the concept still conveys the sense of one's having a vital core that is related to integration in personality.

In self-determination theory (e.g., Deci & Ryan, 1995), an individual's internal processes, structures, and urges can also be described in terms of the extent to which they represent true versus false self. More precisely, we speak of self, or *integrated self*, as that set of coherently organized processes, structures, and energies that are the developmental outcome of organismic integration. All aspects of one's psychological makeup can thus be understood in terms of the degree to which they are integrated. Those that are more integrated are akin to what Winnicott and others called true self.

Autonomy as Authenticity

The term "authentic" typically applies to something that actually proceeds from its reputed "author" (Wild, 1965). Authentic actions are thus ones with which the person identifies and for which he or she accepts responsibility. Accordingly, authenticity can be represented as a continuum describing the extent to which an action is a true expression of one's self (and thus autonomous) versus an expression of pressures or causes external to the self (and thus controlled or amotivated; Ryan, 1993; Ryan & Deci, 2004).

The concept of authenticity has appeared primarily in the writings of existentially oriented philosophers (e.g., Kierkegaard, 1849/1968) and therapists (e.g., Yalom, 1980). The concept is highly apt for describing the phenomenological experience of acting from one's sense of self (Ryan, 1993). When an action is fully endorsed by its au-

thor, the experience is that of integrity or authenticity. As Laing (1969, p. 127) put it, "To be authentic is to be true to oneself." Authenticity is thus acting from the self; it is self-determination. When viewed in this way, authenticity becomes a quality of behavior rather than just an abstract philosophical concept.

Although literatures emphasizing authenticity tend to focus on the behaviors and experiences of adults, the term authenticity can be applied even to very young children. Observation of toddlers in the context of controlling or maltreating families will reveal the sense of surface compliance, as-if affects, and false consciousness as early as the 2nd year of life (e.g., Crittenden, 1988). As Crocker and Litman (1990) argued, there is an important difference between a toddler's doing something compliantly, out of fear or force, and doing it autonomously, with a full sense of willingness. Similarly, Kochanska (1997) differentiated situational compliance from committed compliance. In situational compliance, the child is cooperative but lacks a sincere commitment to the behavior; for the behavior to be sustained, the child needs reminders and prompts. By contrast, in committed compliance, the child appears to accept and endorse the behavior as his or her own; he or she maintains the behavior without prompts or reminders. Committed compliance increases with age and is associated with later indices of internalization such as doing required activities in the absence of adults and resisting enticements to cheat (Kochanska & Aksan, 1995). Clearly, such relatively autonomous (rather than merely compliant) performance of uninteresting, though important activities is a significant goal of socialization.

Of course, with further development, the issue of authenticity takes on even greater salience. With the advent of self-consciousness and adolescent egocentrism (Ryan & Kuczowski, 1994) the potential for presenting an inauthentic self to others and for either hiding or losing touch with one's real or authentic feelings and beliefs is magnified.

The more controlling the social context, the less authentic people are likely to feel, and along with that, the less self-expressive and emotionally integrated they appear to be. That is, authenticity typically depends on a context that supports autonomy. For instance, M. L. Lynch et al. (2004) measured the extent to which individuals in three diverse cultures felt authentic in their relationships to specific significant others, such as mother, father, best friend, romantic partner, and roommates. Results showed that authenticity varied systematically across relationships with the perceived autonomy supportiveness of the other person. Moreover, relationship satisfaction, emotional expressiveness, and self-congruency in trait

behaviors were robustly associated with the experience that partners supported one's autonomy.

Autonomy as Will

Autonomy has also been equated with will by some authors (e.g., Deci, 1980; Easterbrook, 1978), although the concept of will has not been widely employed in the psychological literature. In part, this stems from confusion between the concepts of "will" and "free will," and the crux of the issue has to do with whether behaviors that are willed are free from causation. The philosophical debate between free will and "determinism" concerned whether all behaviors are lawful and thus predictable: Free will was interpreted as meaning freedom from causation, whereas determinism was interpreted as meaning that behavior is lawfully caused.

Although in philosophical literatures this issue is largely passé, the free will versus determinism debate seems to resurface periodically in psychology. Wegner (2002) supplies a good recent example. He defined will as behavior whose original impetus is a conscious thought. He then argued, and in some cases demonstrated, that people are mistaken in attributing actions to will, because even thoughts are caused. Wegner concludes that the whole issue of will may be illusory.

As Ryan and Deci (2004) pointed out, however, the concept of will (as autonomy) does not mean freedom from causation; rather, it refers to the regulation of action that is self-directed and concordant with one's values and beliefs. Behaviors that are willed can certainly be said to be caused or determined, in the senses both that historical forces shape the values and sensibilities with which such behaviors concur and that proximal influences set in motion the specific actions that reflect concordance or integration. Understood in this way, it is entirely possible for a person to experience a sense of will (or autonomy) while engaging in actions that can also be described in terms of their material and efficient causal underpinnings.

The concept of will has long been a part of phenomenological analyses. Thus, Pfander (1908/1967) used a phenomenological approach in distinguishing actions that reflect one's will from other forms of motivated behaving. He argued that acts can be described as willed to the extent that they are experienced as being caused by oneself as agent or emanate from one's "ego-center." In contrast, other forms of action are experienced as caused by forces "outside one's ego-center." Interpreted in this way, only willed acts would be considered autonomous, for only they emanate from one's phenomenal sense of self.

Parenthetically, it is worth noting that the term "will power" is sometimes used to describe the process of countering one's urges or organismic nature through force (e.g., Deci, 1980). May (1969) suggested that will power involves self-deceit, and Shapiro (1981) stated that the use of will power is central to rigid character disorders such as obsessive-compulsive personality. Behavior that is regulated through will power, when the term is used in that sense, would not typically be considered autonomous, as that frequently refers to one part of personality dominating another. Highly introjected people may appear "strong willed," even though they may in fact be pressured, rigid, and overcontrolled in their behavioral regulation.

We believe this nonautonomous regulation represented by will power is what underlies or explains what Baumeister, Muraven, and Tice (2000) described as the *ego depletion phenomenon*. They argued that the exercise of self-regulation is draining, and they reviewed a number of creative experiments demonstrating how the exercise of will depletes energy and the capacity for effort. But the conception of self-regulation they employ is undifferentiated and most closely approximates self-control or what we call introjected regulation. In fact, we propose that autonomous self-regulation is not depleting at all, but instead can be vitalizing, whereas nonautonomous regulation, or self-control, is depleting as they suggest. This effect has also been shown in experimental studies (e.g., Nix, Ryan, Manly, & Deci, 1999). This literature on depletion versus vitality again bespeaks the importance of discerning the degree of autonomy underlying behavior.

Autonomy as Agency

To be autonomous means to act agentically and to experience a sense of choice and willingness in those actions. Agency thus connotes something different from merely deciding to act, for one can "decide" to do what one feels compelled or coerced to do. To convey fully the meaning of autonomy as agency thus requires that we again distinguish between the concepts of intentionality and autonomy.

Intentionality refers to purposefulness, to pursuing a desired outcome. Autonomy, however, is a more restrictive term, for it necessitates the experience of feeling that intended actions are an expression of one's values, abiding sensibilities, and interests. An action would thus be considered intentional, but not autonomous, when one feels one "has to" do it, or when one feels pressured by one's craving for the praise it is expected to yield. When one acts compulsively, for example, whether in aligning the magazines on the coffee table or washing one's hands yet again, the

behavior is intentional, but it is surely not autonomous, for it lacks the sense of freedom and flexibility that are the phenomenological accompaniments of autonomy.

It is worth noting that some theorists do equate agency with intentionality and thus use it in a way that is not consistent with our definition of the term. For example, Bandura (1989) described all self-efficacious or intentional actions as agentic. In other words, from his perspective, to be motivated is to be agentic, whereas for us, a person is truly agentic only to the extent that he or she is autonomously motivated.

It is precisely because humans have the capacity to act other than from their core—that is, to act from fractionated regulatory processes or divided consciousness—that the concept of human agency takes on its import. A person who is a pawn to forces external to the self with which they do not concur, no matter how intentional, is neither autonomous nor really agentic (Shapiro, 1981). Moreover, as R. N. Williams (1992) put it, agency means engaging the world truthfully, free from self-deceit. How little intentional behavior in everyday life fits that description is something each of us can ponder.

An additional use of the term agency, distinct from our usage, portrays agency as self-interest, which is contrasted with communality, in which one puts others before oneself. This usage stems from Bakan's (1966) distinctions for these terms, later applied by Helgeson (1994) and others. Our view would simply be that autonomy is orthogonal to this distinction, as one can be autonomously agentic or autonomously communal, and similarly one can be heteronomously agentic or communal. Moreover, we suspect that what has been called "unmitigated communality" by Helgeson, and that has been linked to depression and "self-silencing," is largely heteronomous communality. It typically reflects an internalization of various forms of oppression.

Human Autonomy: A Reprise

Phenomenologically, autonomy relates to the experience of agency and authenticity, to the experience of an internal perceived locus of causality. Intrinsically motivated activities are autonomous and are typically accompanied by the experience of spontaneous interest and vitality, whereas extrinsic actions characterized by autonomy are more typically represented as enactments of fully integrated values and goals.

Starting with the concept of autonomy as a phenomenological issue has been important in empirical pursuits, insofar as perceived autonomy—that is, an internal perceived

locus of causality—can be employed to help differentiate among different types of motivational processes. As will be seen in the subsequent review of our empirical work, this approach has been validated in two important ways. First, people's perceptions of autonomy are greater in social contexts that support autonomy rather than control behavior (Deci & Ryan, 1987, 2000). Second, people's experience of autonomy has consequences for the quality of behavior, such as persistence, flexibility, and creativity, and for both psychological and physical health (e.g., Amabile, 1983; Grolnick, Gurland, DeCoursey, & Jacob, 2002; Koestner, Bernieri, & Zuckerman, 1992).

The concept of human autonomy applies directly to developmental psychopathology in that failures in self-regulation, manifest as controlling or amotivational processes, represent impairments in the development of self. Although all people display some nonautonomous regulation, excessive and chronic instances of being controlled or amotivated are quite broadly implicated in many specific disorders. Moreover, the pervasive experience of being controlled during early development sets the stage for later difficulties and deficits in the regulation of both action and experience.

WHAT AUTONOMY IS NOT

Having provided a theoretical and definitional overview of autonomy as being based in the organizational tendencies at the heart of development and the corresponding experience of authenticity and volition, we turn to the question of what autonomy is not. We specifically address a variety of related ideas that are often used to either argue against the importance of autonomy or that are inconsistent with our use of the term.

Autonomy as Independence from Environments?

In his social cognitive theory of human agency, Bandura (1989, p. 1175) defined autonomy as action that is "entirely independent" of the environment. If the environment has an influence on behavior, there can be no autonomy, and thus Bandura claims the construct of autonomy to be without merit. The issue of whether there is or is not acceptance, consent, or volition with respect to environmental influences, despite the myriad empirical consequences of acceptance or consent, was simply not addressed in Bandura's argument.

Such a stance is uninformed in terms of the work of many philosophical thinkers (e.g., Dworkin, 1988; Friedman, 2003) who have articulated that autonomy does not

concern the source of the impetus to action, but rather an action's backing by the self—its concordance and its reflective endorsement. Further, Bandura appears to be arguing with a straw man, as we know of no psychologists who consider it necessary for autonomous behavior to emerge independently of supports, prompts, or initiating events.

As noted, by writing off the concept of autonomy, Bandura reduced agency to self-efficacy, without distinguishing those efficacious behaviors that are freely chosen and authentic from those that are pressured and/or not well-anchored within the self. Simply stated, the belief that one can behave so as to successfully control an outcome does not address whether or not one wants to do it or values it—issues that are at the very crux of people's salient concerns about autonomy and agency.

Autonomy as a Denial of Implicit Motives?

Although many clinicians have long recognized that the regulation of some behaviors is nonconscious, there is now growing empirical evidence that actions may be initiated by factors of which people are unaware even when they think they know the causes (Wilson, 2002). Bargh and Ferguson (2000), for example, cited several studies in which people were implicitly or nonconsciously primed to enact intentional behaviors and then attribute their actions to will or self-initiation. Such experiments have been used to suggest that *all* actions may be nonconsciously determined and to question whether the idea of being self-motivated has any veracity.

In our conceptualization, however, the issue of implicit and explicit motivation is largely orthogonal to the issue of autonomous versus heteronomous motivation (Deci & Ryan, 1980b; Ryan & Deci, 2004). Implicit events or cues may prompt either autonomous or controlled behaviors. Further, we suggest that behaviors that are *automatic* (i.e., not consciously experienced or reflected on) may be regulated by either autonomous or controlled processes. A driver who automatically shifts her car into second gear when the cue of engine noise nonconsciously prompts it may be acting fully autonomously. Were she to reflectively consider it, she would wholly endorse her behavior. Conversely, nonconscious or implicit motives can drive heteronomous behavior. A smoker who has made a personal commitment to quit for the sake of his health but, after subliminal exposure to a cigarette ad, finds himself mindlessly pulling out a smoke would be controlled in this action. Were he to reflectively consider this act, he would agree that the behavior was inconsistent with his self-endorsed goals.

Just as nonconscious motives can organize either autonomous or heteronomous actions, conscious or explicit motives can also organize either autonomous or heteronomous behavior. In short, the issues of automaticity versus deliberateness and implicit versus explicit motives does not inform us that well concerning the relative autonomy of actions. Some habits and reactions are ones we would experience as autonomous; others seem alien, imposed, or compulsive, and this consideration is critical in understanding the individual experiences associated with varied psychopathologies.

It is true, however, that people can be more or less mindful or reflective concerning what they have been prompted to do, and this is clearly an aid to ongoing autonomous regulation. This formulation is quite consistent with the experimental findings of Libet (1999), who showed not only that volitional action can be preceded by a readiness potential in the brain before any awareness of intention, but also that consciousness can function to approve (or veto) the commission of the act. Similarly, Levesque and Brown (2003) examined whether mindfulness, or the tendency to be aware of what is occurring in the moment (Brown & Ryan, 2003), would moderate the power of implicit motives. They found that indeed it did: Implicit motivation was a more potent predictor of behavior when mindfulness was low.

Autonomy as Entailing a Disembodied Self?

Often mixed in with the arguments about our ignorance of the actual causes of our behavior is the argument by some that, as we understand more about how the brain is involved in actions, concepts such as will and autonomy become obsolete. Consider this telling passage from Pinker (2002, p. 43), a popular neuroscience author:

Each of us feels that there is a single "I" in control. But that is an illusion that the brain works hard to produce. . . . The brain does have supervisory systems in the prefrontal lobes and anterior cingulate cortex, which can push the buttons of behavior and override habits and urges. But these systems are gadgets with specific quirks and limitations; they are not implementations of the rational free agent traditionally identified with the soul or the self.

Herein Pinker declares the "I" an "illusion," but linguistically replaces it with a new intentional subject, "the brain," which pushes buttons, controls urges, and works hard on creating illusions. For Pinker, the sense of self is just a postbehavior "spin," whereas the brain, reified as if it were an intentional subject, does the governing and gadget pulling. Such interpretations are pervasive in popular neuroscience but are fraught with philosophical confounds.

The logic is that because the brain is always involved in behavior, there can be no “free rational agent” (a construct that itself is something of a straw man). No matter that the brain itself may be stimulated into action by social events, or that the brain’s “quirky gadgets” are mediated by people’s psychological interpretations and meaning construction, or that active reflection can alter those meanings.

More generally, it is our view that all events in the universe can be described in material-efficient or causal terms, and this applies to all behaviors as well. Whether a behavior is autonomous or controlled, it requires a brain. However, even at the level of the brain, we believe the dynamics of autonomous regulation differ from those of controlled regulation (Ryan et al., 1997), and increasingly, neuropsychological evidence supports this view. Indeed, it is pretty clear that autonomy typically requires the involvement of executive systems in the right prefrontal cortex, as well as afferent and efferent connections with a variety of emotional centers, and moreover that damage to specific sites can disrupt capacities for volition and valuation of intentions (Ryan, in press). This does not reduce the issue of autonomy to merely a neurological event, but it does suggest the importance of coordinating our understanding of behavioral regulation with brain research (e.g., Walton, Delvin, & Rushworth, 2004). This coordination will, however, require an acknowledgment of bidirectional causation and a sophisticated understanding of the multiple levels of causal analysis that are required to explain social behavior (see Cicchetti & Dawson, 2002; Ryan & Deci, 2004).

Autonomy as Independence from Others?

Perhaps the most common alternative usage of the word autonomy equates it with “independence.” Although autonomy and independence do overlap in their secondary dictionary definitions, they can refer to quite distinct attributes. *Independence* typically refers to not relying on others. Its opposite, dependence, correspondingly means being provided or cared for by others (Memmi, 1984). In contrast, autonomy as we use it describes being self-initiating and feeling a sense of freedom or volition. Its opposite, heteronomy or control, conveys that actions stem from forces external to the self, as when one is pressured or coerced.

Once these distinct definitions are clarified it is easy to see how it is possible for various configurations to arise: One could feel heteronomously independent, heteronomously dependent, autonomously dependent, or both autonomous and independent. The first category applies when one feels forced to give up reliance on another. The second pertains to one’s feeling compelled to rely on an-

other. The third is possible when one volitionally and willingly enters into or accepts dependence or interdependence. And the fourth is conceivable when one desires and initiates self-reliance, or freedom from reliance on others.

When dependence (versus independence) is viewed in terms of relying on (versus not relying on) others, dependencies of varied sorts can be construed as potentially autonomous at all stages of development. Newborns are highly dependent, and as they grow older, they become gradually less dependent in many respects, but there are significant areas of dependence that remain and are appropriate throughout youth. Moreover, there is no point in the life span in which persons are not at least interdependent. The important issue, therefore, is whether a person’s dependence, whatever its level and at whatever stage of development, is experienced as autonomous or controlled. It is possible for someone to be provided for—that is, to be dependent—with a full sense of willingness and volition, just as it is possible to feel pressured or coerced in one’s dependence. This does not detract from the recognition, however, that the issues of dependence and autonomy can dynamically interact, as when caregivers use their resources as instruments of control, or when people are taught that dependency is “bad.” Similarly, being independent does not ensure autonomy, for one can be pressured into independence, as when a child is forced to “do for one-self” by parents with immoderately high expectations, as often happens, for example, in the development of paranoid personality disorders (Sperry, 2003).

The conceptual demarcation between independence and autonomy is a crucial one not only for developmental thinking, but also for theories of gender and cultural differences. Numerous writers have denigrated the importance of autonomy, suggesting that too much self-reliance is unnatural and unhealthy. For example, the masculine (Gilligan, 1982; Jordon, 1991) and Western (Markus et al., 1996) casts toward noninterdependence and individualism have often been criticized under the rubric of autonomy. As critiques of extreme independence, these arguments may have considerable merit, but they are not meaningful critiques of autonomy. To construe autonomy as an exclusively male and/or Western cultural value and preoccupation is to inappropriately equate autonomy with nonreliance. This unfortunate confusion runs the risk of denying the importance of volition and authenticity to women and non-Western persons, which, of course, constitutes a regressive and potentially disempowering political (see Friedman, 2003) and clinical (see Lerner, 1988; Ryan, 1991) stance. It also precludes an ideal of many relational theories that recognize mutuality of autonomy and volitional interdependence.

cies as optimal forms of interpersonal engagement (see Deci et al., 2004). Finally, it ignores the growing evidence that across cultures, the extent to which people internalize and integrate cultural practices, and therefore embrace them autonomously, matters greatly for mental health and cultural fit (e.g., Chirkov et al., 2003).

Autonomy as Detachment or Separation?

Human beings, out of their innate need for relatedness, are oriented toward attachments with caregivers (Bowlby, 1969), just as they begin immediately to express and strive for greater autonomy. As we argue in SDT, both relatedness and autonomy are fundamental needs. Still, some theorists have cast the development of autonomy in terms of relinquishing attachments, especially during adolescence (e.g., Blos, 1962; Freud, 1958; L. Steinberg & Silverberg, 1986). In doing this, they are construing autonomy in terms of detachment and separation rather than volition and self-regulation. In addition to the conceptual confusion this creates, there is the empirical fact that detachment (especially from parents) is typically counterproductive with regard to the development of autonomy and self-regulation.

Ryan and Lynch (1989) applied this formulation in their reconsideration of research by L. Steinberg and Silverberg (1986) on what the latter authors termed *emotional autonomy* in adolescence. Steinberg and Silverberg drew on Blos's (1962) theory of adolescence, defining emotional autonomy as the relinquishing of dependence on parents, and they developed a measure to assess this construct. Ryan and Lynch, while acknowledging the significance of reliance issues in adolescent development, criticized the labeling of such nonreliance as autonomy. They regarded the so-called emotionally autonomous youths as those who, for a variety of reasons, indicate less willingness to turn to their parents for support, guidance, or help. Rather than indicating volition and agency, such attributes could be better interpreted as emotional *detachment*.

Ryan and Lynch (1989) further suggested that under most circumstances, teenagers who detach from and thus do not utilize or rely on their parents for emotional support would tend to show more negative developmental consequences, whereas autonomy (i.e., volition) has been shown to have positive consequences. Supporting their view, Ryan and Lynch showed in varied adolescent samples that a high degree of what was labeled emotional autonomy by L. Steinberg and Silverberg (1986) was negatively correlated with indices of adjustment such as self-esteem, perceived competence, and lovability. Autonomy, in contrast, has frequently been found to be positively correlated with those

same indices (Deci & Ryan, 2000). Further, Ryan and Lynch provided evidence that the familial contexts associated with high degrees of adolescent emotional autonomy were those lacking in cohesion and support and characterized by insecure attachments. Such evidence points toward both the positive confluence of attachment and autonomy and the importance of differentiating the idea of autonomy from that of detachment and independence. Specifically, a good deal of emotional attachment to caregivers is, according to Ryan and Lynch, conducive rather than antithetical to autonomy and healthy development.

Subsequently, Lamborn and Steinberg (1993) altered their position to suggest a moderation effect. They argued that emotional autonomy as they defined it is beneficial for adolescents who have very high levels of parental support but not for those with less optimal parental supports. Yet, the data they presented nonetheless showed a robust main effect in which emotional autonomy predicts negative well-being, compared to a weak moderation effect. Moreover, these results were subsequently contradicted by Fuhrman and Holmbeck (1995), who showed the same main effect, but an opposite pattern of moderation: Emotional autonomy was more beneficial to teens whose parents were low in support. That is, it appeared better to detach from unsupportive or unreliable parents.

We agree that, under the adverse circumstances of non-nurturant parents, detachment may have some value, and we even agree that, in the presence of very high support, emotional autonomy may represent a type of healthy independence. However, such arguments miss the point of Ryan and Lynch's (1989) original argument that emotional detachment (1) is not the same as emotional or behavioral autonomy and (2) is a nonoptimal developmental course. Indeed, several studies have shown that emotional autonomy is higher when parents are nonnurturing and in families that lack cohesion. In addition, children high in emotional autonomy are more likely to conform to peers, engage in risky behaviors, and achieve less well in school (e.g., McBride-Chang & Chang, 1998; Turner, Irwin, Tschann, & Millstein, 1993). All of this makes sense if emotional autonomy is detachment, but not if it is autonomy.

To be clear then, we do not just argue that L. Steinberg and Silverberg (1986) have mislabeled their construct. We disagree with the original formulation by Freud (1958), Blos (1979), and others who have advocated that detachment or emotional disengagement from parents is in any way a necessary or positive trend in normal development. No doubt, teenagers do become more independent, and sensitive parents can support the development of these competencies. But insofar as parents support the child's autonomy,

no emotional detachment need occur. Moreover, our view is that autonomy coexists with dependence and interdependence throughout the life span. In short, a differentiated approach to autonomy need not pit it against attachment or dependence.

Autonomy as Just a Stage?

The development of autonomy, when viewed as an increasing capacity for volition resulting from the integration of regulatory processes, is ongoing throughout life. The form and content of autonomous regulation vary at different developmental stages, but the issue is ever pertinent with respect to mental health. Various writers, however, have portrayed the struggle for autonomy as being primarily evident at, or restricted to, particular developmental stages. We turn to a consideration of some stage models.

Erikson

Perhaps the best known of such theories is Erikson's (1950) theory of psychosocial development. Erikson identified the 2nd and 3rd years of children's lives as a critical period for the development of autonomy. At this time, having achieved a primitive sense of self as a separate entity, children begin to assert themselves, generally in accord with their biological urges, but at times, as all parents know, apparently just to be oppositional, to oppose the word or will of others. Erikson argued that, if allowed to respond to their urges and inner cues, children will develop a sense of autonomy and pride. By contrast, if they face rigid dominance and are not allowed to act on their drives and desires, they will instead develop a sense of shame and doubt. In such cases, they may find it necessary to block awareness of their own inner cues and develop a more passive stance toward the initiation of behavior.

We agree that this period in children's lives, when their sense of self is still quite rudimentary, is crucial for their long-term sense of autonomy, and the responsiveness of the social context is critically important for that development. However, the struggle for autonomy is ongoing across the life span, and although Erikson's theory acknowledges the importance of integration throughout one's life, his relegating the concept of autonomy development to this brief stage diminishes greatly the meaning of autonomy. The dynamic in which people attempt to be self-regulating—to assert their autonomy—and are responded to in either an autonomy-supportive or a controlling manner is played out at all stages of life with regard to varied issues and in varied domains. Our research has consistently shown that the social context's being autonomy-supportive versus control-

ling of people at various ages affects not only their immediate motivation but also their ongoing tendencies to be autonomous.

Piaget

Piaget (1967) suggested that will (which is closely related to autonomy) is a regulatory capacity that comes into existence during middle childhood (7 to 12 years of age) in relation to moral issues. For a child of that age, morality is gradually shifting from being based wholly on authority to being determined more by mutuality and consent. The shift away from exclusive reliance on authority necessitates the development of internal regulatory processes that, as Piaget conceived it, allow a morally superior principle to win out over a morally inferior drive. In our view, this process of developing internal regulatory processes to manage one's drives and emotions is merely an example of developing one's more general sense of will or autonomy and is one that begins before and continues long after middle childhood.

Anna Freud

Anna Freud (1958) is among the earliest thinkers to conceive of autonomy as a "developmental line." Yet, she also focused on adolescence as the important period for the development of autonomy. As noted, adolescence is a period of individuation in which teenagers develop both greater independence and greater autonomy. However, it is the rebellion of a child struggling to free himself or herself from parental control that is often said to reflect autonomous regulation. Rebellion, which typically means insistently doing the opposite of what was demanded of one, does not, however, constitute autonomy. Instead, rebellion is merely the defiant rather than compliant form of being controlled and is not accompanied by the experience of choice, volition, and coherence. The period of adolescence is surely important for the development of autonomy for, as teenagers gradually individuate from parental authority, they are faced with the challenge of developing the type of internal regulatory processes that constitute autonomous rather than controlled regulation. However, as with the struggles in early and middle childhood, this represents one aspect and form of the striving for autonomy that is central to development across the life span.

Loevinger

Finally, Loevinger (1976) used the term autonomy to describe a stage of adulthood that most individuals never attain. This stage is characterized by the ability to accept responsibility for one's actions and emotions and to act out

of well-synthesized or integrated social prescriptions. Her description of autonomy thus bespeaks the concepts of integration and awareness that indeed are the hallmarks of mature self-determination. Still, these characteristics can be found to varying degrees in behavior at all ages, not only in some people during adulthood.

These various theories all emphasize the importance of people's striving for autonomy, but they localize the struggle to specific, though different, developmental epochs, ranging from infancy to adulthood. When taken together, however, the theories highlight how significant the dynamics of autonomy are across all stages of development. In infancy, autonomy concerns the consolidation of self and the development of initiative. Progressively, as the child gets older, autonomy relates to assimilating socially important behaviors and ideals while preserving one's initiative, to individuating and forming new attachments while preserving the old, and to fully accepting oneself and respecting the initiative of others. In all cases, the issues concern reaching an accommodation to the social world in a way that allows an internal perceived locus of causality and the experience of agency and volition.

THE SUPPORT OF AUTONOMY AND THE FACILITATION OF DEVELOPMENT

Having conveyed what is (and is not) meant by autonomy, we turn now to an elaboration of the role of autonomy in development and to the factors in social contexts that facilitate or undermine it. To do so, we focus on four developmental processes in which autonomy figures heavily: intrinsic motivation, internalization, attachment, and emotional integration.

Intrinsic Motivation

Intrinsic motivation is an attribute with which humans are liberally endowed and which plays an extremely important role in psychological development. Intrinsic motivational tendencies are evident in the active exploration, manipulation, curiosity, and exercise of skills that foster the growth of competencies, as numerous developmental theorists have argued (e.g., Bruner, 1962; Flavell, 1977; Harter, 1993; White, 1963). Also known as mastery motivation (e.g., Ryan & Connell, 1988), this motivational propensity is evident well before a child's first birthday (Ainsworth, Blehar, Waters, & Wall, 1978; Yarrow, Rubenstein, & Pedersen, 1975) and differentiates into more specific interests as the child grows older (Deci &

Ryan, 2000). These innate or natural tendencies are intrinsically motivated in the sense that they require no incentives or pressures but instead occur spontaneously when the social context does not forestall them (Deci & Ryan, 1985b). Intrinsically motivated activities provide their own rewards in the form of the excitement, interest, and enjoyment that accompanies them. They are in this sense autotelic (Csikszentmihalyi, 1975) rather than being instrumental for some separable consequence.

The concept of intrinsic motivation emerged from the experimental literature during the 1950s and 1960s in opposition to the dominant behavioral theories of that period, namely operant theory and drive theory, both of which viewed all behavior as controlled by contingencies of reinforcement. In drive theory behaviors were said to be motivated through reinforcements associated with drive reduction (Hull, 1943). Operant theory (B. F. Skinner, 1953) similarly proposed that all operant behavior is under the control of contingencies of reinforcement in the environment; in other words, all nonreflexive behaviors are maintained by extrinsic consequences. Proponents of intrinsic motivation (e.g., Harlow, 1953; White, 1959), in contrast, held that there are many behaviors, such as play and exploration, that are "rewarding in their own right," or done out of interest and do not require separable extrinsic rewards or reinforcements (Deci & Ryan, 1980a). This conceptualization of an innate and natural source of activity oriented toward the exercise and growth of capacities has ever since been an important coordinate for the study of developmental and learning processes (Elliot, McGregor, & Thrash, 2002; Koestner & McClelland, 1990; White, 1959).

In our research on intrinsic motivation, we work with the general thesis that intrinsic motivation represents an autonomous organismic striving and is accompanied by people's experiencing their actions as emanating from themselves, as having an internal perceived locus of causality (Ryan & Deci, 2000b). We also reason that, although intrinsic motivation is "natural," it is highly dependent on social conditions that help to support and preserve it. Thus, intrinsic motivation—and the curiosity, assimilative tendency, and joy that attend it—have been predicted to be undermined in conditions that are overly controlling or inconsistent, leading to nonoptimal development and, in extreme cases, the onset of stagnation and psychopathology.

Numerous studies, using widely varied methods, have linked intrinsic motivation to effectively negotiating one's surroundings. For example, children's intrinsic motivation has been positively related to creativity (e.g., Amabile, 1983; Koestner, Ryan, Bernieri, & Holt, 1984), and both el-

elementary school and college students' intrinsic motivation has been positively associated with fuller processing of information and greater conceptual understanding (Benware & Deci, 1984; Grolnick & Ryan, 1987). For example, in a recent experiment, Grolnick et al. (2002) observed mothers and their third-grade children working on poems. Following the interaction, children were asked to complete similar tasks on their own. Children whose mothers interacted with them in a more controlling manner performed just as well as other children when they were with their mothers, but, when completing tasks on their own, the children of more controlling mothers were less accurate in solving the problems and wrote less creative poems. Such studies indicate that undermined intrinsic motivation can have negative consequences for learning, persistence, and performance across a person's first 2 decades.

Even more important, perhaps, individuals' intrinsic motivation has been positively related to mental health. For example, children's intrinsic motivation in a classroom setting has been positively associated with feelings of self-worth (e.g., Deci, Schwartz, Sheinman, & Ryan, 1981; Ryan & Grolnick, 1986). Lower levels of intrinsic motivation have been linked to more aggressive projections (Ryan & Grolnick, 1986), more maladaptive coping (Ryan & Connell, 1989; E. Skinner & Edge, 2002), more tension and anxiety (e.g., Ryan, Mims, & Koestner, 1983), and more negative emotional tone (Garbarino, 1975). These and related studies suggest that when intrinsic motivation is undermined, some adverse consequences for wellness can follow. Because of these effects on both growth and well-being, it seems important to explicate the social-contextual conditions that enhance versus undermine intrinsic motivation.

The Social Context and Intrinsic Motivation

A substantial amount of research has explored the effects of various social contexts on intrinsic motivation, which has been described in a specific minitheory of SDT, cognitive evaluation theory (CET; Deci & Ryan, 1980a). In brief, CET argues that intrinsic motivation is dependent on experiences of both autonomy and competence in action, and thus environmental controls and/or nonoptimal challenges will undermine intrinsic motivation. Studies based on CET have been done with participants ranging from toddlers to adults, allowing us to draw inferences about fundamental, cross-age, aspects of intrinsic motivation.

One type of evidence comes from experimental studies. In the typical paradigm, there are groups of participants working on the same activity under different conditions (usually varied in terms of factors affecting perceived au-

tonomy, perceived competence, or both). Subsequently, intrinsic motivation is assessed by placing participants in a free-choice situation where the target activity is available, as are alternative activities. The amount of time participants spend spontaneously engaging in the target activity is recorded and used as the free-choice or free-play measure of intrinsic motivation. Ratings of how interesting and enjoyable participants found the task are used as a secondary measure of intrinsic motivation. When these two measures are significantly correlated, we are most confident that the free-choice behavior is a true reflection of intrinsic motivation (Ryan, Koestner, & Deci, 1991).

In the earliest studies, Deci (1971, 1972) found that participants who received monetary rewards for solving interesting puzzles subsequently displayed significantly less intrinsic motivation than those who had solved the puzzles for no rewards. Deci (1971) postulated that rewarded participants were more likely to see the impetus or "cause" of their activity as stemming from external, as opposed to internal, sources, thus prompting a shift in their perceived locus of causality. This proposal was provocative precisely because so many psychologists had emphasized that rewards are the primary impetus behind individual behavior. Here, not only was that not the case, but rewards were shown to have a detrimental effect on spontaneous challenge-seeking behaviors.

A study by Lepper, Greene, and Nisbett (1973), in which preschool children were given good-player awards for drawing with magic markers, found results complementary to those of Deci (1971, 1972). Lepper et al. not only showed the generalizability of the undermining of intrinsic motivation by rewards to young children, they also showed that the negative effects persisted across a considerable delay period. A plethora of studies soon converged on this point, documenting that the allure of attractive extrinsic rewards can have a negative effect on people's autonomy. People gradually become "pawns" to the rewards (deCharms, 1968), and their intrinsic motivation is undermined.

The undermining effect of rewards on intrinsic motivation has been, for some behaviors, a flash point for debate. In the early 1980s, there were numerous studies attempting to account for the effect in behavioral terms, most of which failed to provide a convincing counterargument (see Deci & Ryan, 1985b, for a review). The message of a voluminous literature was clear, as meta-analyses began to show. However, the debate was resparked by an *American Psychologist* article about reward effects on intrinsic motivation in which Eisenberger and Cameron (1996) claimed that rewards, regardless of whether they are controlling or informational as cognitive evaluation theory classifies them, do

not have negative effects and need not be a source of concern. Despite prior meta-analyses finding support for CET's position, Eisenberger and Cameron claimed that their new analyses showed there was no compelling evidence for an undermining effect by rewards in spite of the accepted view. Detecting a problem, Deci, Koestner, and Ryan (1999) reanalyzed the experimental data, encompassing the studies used by Eisenberger and Cameron, and presented some startling findings. Results detailed how Eisenberger and Cameron's analyses were plagued by miscalculations, inappropriate collapsing of conditions across moderators, incorrect reporting of effect sizes, misclassifications of conditions, and employment of the wrong control groups. The errors were extensive, but when corrected, a quite different picture emerged than that claimed by Eisenberger and Cameron. The results showed an overall significant undermining of intrinsic motivation by rewards, but even more important, the matrix of reward effects on intrinsic motivation was perfectly fitting with the differentiated predictions of CET concerning when rewards should and should not undermine intrinsic motivation. Eisenberger, Pierce, and Cameron's (1999) invited response did not dispute Deci et al.'s primary findings.

What makes this controversy odd, however, is that, from the SDT perspective, we have never doubted the power of external rewards and reinforcements to control behavior. It is rather that, because of their power to control, rewards can lead children away from their intrinsic inclinations, away from behaving authentically in accord with abiding values and interests. Arbitrary rewards, if compelling enough, can get people to do almost anything. Indeed, no one who looks at the reality of today's reward-based economies should doubt that powerful extrinsic rewards can lead people to forgo autonomy, forget their values and needs, and neglect their attachments. That is precisely what unhealthy regulation and alienation is all about (Ryan & Deci, 2000a).

Not only can controlling rewards undermine intrinsic motivation, but so can coercive motivational tactics, such as manipulative praise (Ryan, 1982) and threatened punishments (Deci & Cascio, 1972). Further, surveillance (Lepper & Greene, 1975; Pittman, Davey, Alafat, Wetherill, & Kramer, 1980; Plant & Ryan, 1985), evaluations (Smith, 1974), and controlling language (Ryan, 1982) have also been found to decrease intrinsic motivation. In these studies, the external events employed (e.g., reward, surveillance, threat, controlling language) are those that are frequently used as methods of controlling behavior. The common element in these events is their psychological meaning, or *functional significance*, of being controlling, which in turn tends to negatively affect people's sense of autonomy.

Although material rewards are not widely used during the early years of a child's development, the use of controlling interpersonal rewards is very prevalent. Parents, for example, often use controlling directive language and "withdrawal of love" to shape their children's attitudes and behavior (Grolnick, 2002). The general point of this literature is that, to the extent that adults use these salient prods, prompts, or pressures to induce performance of an interesting activity, they are likely to disrupt intrinsic motivation and autonomous functioning, which may in turn result in a variety of nonoptimal outcomes (Assor, Roth, & Deci, 2004).

The significance of this idea for development cannot be overstated. Children's exploration, challenge seeking, and curiosity with respect to the physical and social worlds, from which specific competencies derive, appear to be curtailed in an impinging, contingency-managed environment. Intrinsic motivational tendencies supporting growth can, it appears, be stifled by well-meaning caretakers who attempt to elicit development through reinforcement or control. Thus, even though, as Piaget (1952), Bruner (1962), and many others have emphasized, the tendency toward assimilation is a basic fact of psychic life, such findings suggest that even this basic fact requires circumstances supportive of autonomy and competence to remain vital and active.

A classic study illustrating this principle was performed by Danner and Lonky (1981). They preclassified children with regard to their current level of cognitive development using Piagetian tasks. They then had children work on these tasks either for or without rewards. Subsequently, they allowed the children to choose activities freely during a play opportunity. When free to choose activities at any level of complexity, unrewarded children gravitated to tasks that were optimally challenging—to those just exceeding their cognitive capacities. However, children who were extrinsically rewarded for problem solving tended to avoid challenges, even during free-choice play. Such results illustrate how attempts to "enhance" development through rewards can clearly backfire (see also Grolnick, 2002; Kruglanski, Stein, & Riter, 1977; Pittman, Emery, & Boggiano, 1982). These studies underscore the idea that developmentally relevant activity has its own fuel and requires conditions supportive of autonomy, rather than external controls, to be sustained.

It is particularly troubling, therefore, that the use of controlling strategies is so pervasive in our modern world because it seems to bring about a general shift away from people's active, autonomous engagement with their surroundings toward a more passive and rigid orientation (e.g.,

Deci et al., 1981; McGraw & McCullers, 1979). By attempting to move children to develop through rewards, trophies, competition, and self-esteem pressures, rather than through support of inherent developmental resources, we all too often run the risk of interfering with what we hope to promote (Kohn, 1996).

Some studies have considered whether any external events will enhance rather than undermine the sense of autonomy essential to intrinsic motivation and related psychological processes. For example, Zuckerman, Porac, Lathin, Smith, and Deci (1978) had college student participants work on interesting puzzles. Half were allowed to make task choices, and, using a yoking procedure, half were assigned the tasks selected by those in the choice condition. Results indicated that participants who had been afforded choice were significantly more intrinsically motivated than those who had not. Swann and Pittman (1977) found similar results with children.

A second external event that has had positive effects on intrinsic motivation is acknowledging the individual's feelings. For example, Koestner et al. (1984) found that when setting limits for early elementary school children, their intrinsic motivation remained high for the activity if their feelings of not wanting to observe the limits were acknowledged, whereas their intrinsic motivation was significantly lowered when their feelings were not acknowledged. A study by Deci, Eghrari, Patrick, and Leone (1994) found that acknowledging college-age participants' conflicting feelings also led to more autonomy and a more positive emotional tone than not acknowledging their feelings. Taken together, such studies indicate that providing choice and acknowledging feelings enhances intrinsic motivation and positive affect because these events leave participants feeling less pressured and more autonomous.

In sum, numerous experiments suggest that contextual conditions that are experienced as *controlling* (i.e., as pressure to think, feel, or behave in specific ways) undermine autonomy, resulting in less self-initiation and greater psychological rigidity. In contrast, contextual conditions that are *autonomy-supportive* (i.e., that take the target individual's frame of reference, providing choice and encouraging self-initiation) have positive effects on intrinsic motivation. Extrapolating from this, it is easy to predict that contexts that are overly controlling rather than autonomy-supportive represent one identifiable input to nonoptimal developmental outcomes.

Although it is not the central focus of this chapter, it is worth noting that numerous studies have shown that persistent feedback indicating incompetence at a task or in an activity domain undermines both intrinsic and extrinsic

motivation (e.g., Deci, Cascio, & Krusell, 1973; Hiroto & Seligman, 1975; Koestner & McClelland, 1990). We refer to contexts that continually signify incompetence, potentially resulting in helplessness and depression, as *amotivating*. Indeed, pervasively critical caregivers can lead to the internalization of a sense of self that is incompetent (e.g., Strauss & Ryan, 1987), resulting in a variety of psychological disturbances.

Field Studies

Numerous field studies of parents and teachers have investigated the effects of controlling versus autonomy-supportive social structures on intrinsic motivation. We review some exemplary ones that illustrate effects at different ages.

Grolnick, Bridges, and Frodi (1984) in a study of infants found that those whose mother was more controlling evidenced less mastery motivation and persistence in independent problem solving than did those whose mother tended to support and encourage their initiations and autonomous play.

Deci, Driver, Hotchkiss, Robbins, and Wilson (1993) found similar results in a sample of 5- to 7-year-old children. They reported that mothers who, during an interactive-play period, were rated as being relatively controlling had children whose subsequent intrinsic motivation was lower than those whose vocalizations were rated as more autonomy-supportive.

Deci et al. (1981) found comparable results for late elementary school teachers and their students using teacher self-reports about motivational strategies. When teachers were oriented toward supporting autonomy, the students displayed higher levels of intrinsic motivation, perceived cognitive competence, and self-esteem, whereas when the teachers were oriented toward controlling behavior, the opposite results were obtained. Ryan and Grolnick (1986) reported similar results using children's perceptions of teachers, as did Flink, Boggiano, and Barrett (1990), who also found that when teachers were more controlling students performed less well.

The results of such field studies cohere on several points. When people in positions of responsibility or authority—for example, parents and teachers—support the autonomy of those with whom they interact, the latter individuals tend to display enhanced autonomy, intrinsic motivation, and self-regard. Overcontrol, conversely, is typically associated with diminished motivation and self-esteem. It is noteworthy that the results of these field studies parallel the results of laboratory experiments in which autonomy-supportive versus controlling interpersonal climates were created.

Internalization

When intrinsically motivated, children do what interests them, whether it be exploring a novel space, building a model, or playing with a doll. Although a source of delight for caretakers, it is also a challenge. Often, caregivers think it important to redirect the children's attention and energy away from what interests them to other activities that promote family harmony, improve school performance, or are socially sanctioned. There are many activities, in fact, that children may not find intrinsically interesting but that parents, school systems, and society believe are in the children's best interest. It is thus the task of parents and teachers, as primary socializing agents, to encourage children not only to perform such nonintrinsically motivated activities, but also to aid them in developing internal motivation and willingness to do so.

The shift from an external impetus and sustenance of behaviors to an internal one is characterized herein as the process of *internalization* (Ryan, Connell, & Deci, 1985). Internalization is the means through which someone can become more autonomous in performing an activity that was initially externally prompted. It is an active process of taking in regulatory processes and transforming them into personal values or motivational propensities (Meissner, 1988; Ryan, Connell, et al., 1985; Schafer, 1968).

Internalization is an instance of organismic integration. It is the means through which people, by integrating experiences and the regulatory processes implicit in them, can become more autonomous while at the same time more homonomous, or integrated into one's social world (Angyal, 1965). Through internalization, people acquire values and behaviors that allow them to be effective, to relate to others in a community, and to experience a true sense of willingness in doing so. In other words, internalization functions primarily in the service of people's needs for competence, autonomy, and relatedness, and through effective internalization people become both more homonomous and more autonomous. Conversely, failures of internalization typically imply less effective functioning and vulnerability to alienation and psychopathology.

Because internalization operates in the service of these three basic psychological needs, we can readily predict that aspects of the social context that support autonomy, are adequately structured to support competence, and provide caring interpersonal involvement supporting relatedness will facilitate internalization. When the context allows satisfaction of these needs, and particularly when they are not in any way pitted against each other, there will be optimal socializing circumstances for children to natu-

rally acquire social values subserving nonintrinsically motivated activity.

Conceptualized in this way, one can see that both intrinsic motivation and internalization are related to the construct of autonomy. Intrinsic motivation is the prototype of autonomous regulation, and internalization and integration represent the means by which activities that are not intrinsically interesting can become more autonomous. By integrating values and regulatory processes into one's self, those values and processes become the basis for self-determination of extrinsically motivated (i.e., instrumental) activities. And, although behaviors for which the regulatory processes have been fully integrated do not necessarily become intrinsically motivated (because they retain their instrumental rather than autotelic nature), the more closely the qualities of one's extrinsically motivated behaviors match those of intrinsically motivated behavior, the more likely it is that the extrinsic regulation has been integrated.

In developmental terms, infants express their autonomy through intrinsically motivated engagement and mastery. Gradually, as they develop into toddlerhood, childhood, and adulthood, their autonomous activity is expanded by the integration of regulatory processes that originally had an external impetus or source. It may well be that adults express less intrinsically motivated behavior than children, and instead more frequently display their autonomy in the form of integrated regulation.

When functioning optimally, the internalization process results in values and regulations that are fully integrated with the self. We hypothesize that supports for autonomy and relatedness are necessary for such optimal internalization. Unfortunately, these ideal contextual conditions are not widely prevalent, and full integration of regulations is not often attained. Instead, when socializing agents are too controlling or uninvolved, the internalization process operates nonoptimally, resulting in values and regulations that are only introjected or that remain externally regulated (Ryan, 1993).

Introjection is only partial assimilation in which the internal regulatory process retains essentially the same form it had when it was still external. Perls (1973), for example, vividly described introjection as a process in which some aspect of the environment is "swallowed whole" and never "digested." Metaphorically, it is as if the regulator and regulatee were still separate, even though they are the same person; the regulatory process has *not* been integrated with the self and is thus a source of tension and inner conflict. When a regulation has been introjected (rather than integrated), it tends to be rigid and controlling. Indeed, intro-

jection supplies the developmental basis for *internally controlling* regulation, such as that evidenced in ego involvement (Ryan, 1982). Several studies have now demonstrated that introjection is related to anxiety, self-derogation, and other maladaptive patterns, whereas fuller integration is associated with more positive adaptation (e.g., Ryan & Connell, 1989; Ryan, Rigby, & King, 1993). This suggests, of course, that to the extent that values and regulatory processes are stuck in the form of introjects, a child is at risk for psychopathology.

The importance of distinguishing types of internalization is crucial for developmental theories concerned with the nature and quality of behavioral and psychological functioning. Even in early life it is clear that infants and young children can be either self-regulating or merely compliant. As Crockenberg and Litman (1990) detail, there is a significant difference between a toddler's behaving compliantly, out of fear or force, and behaving autonomously, with a sense of willingness. It is the autonomous performance of uninteresting, though important, activities that should be a goal of socialization. Kochanska's (1995) differentiation of situational compliance from committed compliance reflects a similar perspective.

To provide a framework for making distinctions among various types of internalization, we have specified four regulatory styles that are pertinent to extrinsically motivated behavior (Deci & Ryan, 1985b). *External* regulation describes extrinsically motivated behavior that is initiated and maintained by external rewards and/or punishment avoidance. A girl who does her chores to avoid parental wrath would be externally regulated, as would a child who does them to get rewarded. When an external regulation

has been internalized but not accepted as one's own, it is said to be *introjected*. A boy who cleans up his room because he thinks he should—because that is what “good boys” do—would have introjected the regulation. Gradually, as a child identifies with a value or regulatory process, the child begins to accept it as his or her own. In such cases, the behavior is governed by what we call *identified* regulation, which can be viewed as transitional between introjected and integrated regulation. A girl who studies arithmetic because she believes it is important for her self-selected goal of becoming an architect would be considered identified in terms of this regulation. Finally, *integrated* regulation is the most advanced form of internalized regulation and indicates that a value and its accompanying regulatory process have been reciprocally assimilated with all other aspects of one's self. The internalization process will have been completed, representing further development of one's self. A young man who identifies with working hard at his studies and also identifies with being a good soccer player, and who has organized these differing values within a relatively harmonious regulatory network, can be said to have integrated these regulations.

These varied forms of behavioral regulation are schematically depicted in Figure 20.1. As seen, the four styles of extrinsic motivation can be placed along a continuum of relative autonomy, where external regulation is the least autonomous and integrated regulation is the most autonomous form of extrinsically motivated behavior.

Ryan and Connell (1989) assessed children's external, introjected, and identified regulatory styles for doing schoolwork, as well as their intrinsic motivation. Data confirmed that the external, introjected, identified, and intrinsic

Figure 20.1 The self-determination theory model of internalization.

sis subscales formed a simplex-like pattern, indicating that these four regulatory styles can be ordered along a single dimension of autonomy. The more autonomous styles (identified and intrinsic) were positively correlated with positive affect and proactive coping, whereas the less autonomous styles (i.e., external and introjected) were correlated with negative affect and maladaptive coping. Introjection, in particular, was highly correlated with anxiety and with anxiety amplification following failure, thus highlighting the inner stress and vulnerability caused by these controlling prescriptions.

Ryan and Connell (1989) also found that more autonomous regulation in the prosocial domain was associated with greater empathy, more mature moral reasoning, and more positive relatedness to others, thus signifying the importance of autonomous self-regulation for healthy adaptation in the prosocial as well as the academic domain.

Ryan, Rigby, et al. (1993) examined the degree of internalization of religious values in late adolescents and adults. Results indicated that introjected regulation of religious behaviors was positively associated with symptoms of depression and anxiety and with low self-esteem, whereas identified regulation was negatively associated with these indicators.

Blais, Sabourin, Boucher, and Vallerand (1990) assessed adults' reasons for maintaining their primary relationship, using six types of reasons that vary in their degree of autonomy: amotivational, external, introjected, identified, integrated, and intrinsic. They reported, from a sample of 63 heterosexual couples, that the three regulatory styles constituting non-self-determination (i.e., amotivational, external, and introjected) all correlated significantly negatively with dyadic adjustment and general marital satisfaction. In contrast, the three regulatory styles constituting greater autonomy (i.e., identified, integrated, and intrinsic) all correlated significantly positively with those variables.

Work on self-regulation using the constructs outlined earlier is continuing in the domains of religion (O'Connor & Vallerand, 1990), health care (Ryan, Plant, & O'Malley, 1993; G. C. Williams, Grow, Ryan, Friedman, & Deci, 1996), aging (V. G. Kasser & Ryan, 1999; Vallerand & O'Connor, 1989), education (Grolnick, Ryan, & Deci, 1991; Vallerand & Bissonnette, 1992), and relationships (Deci et al., 2004), among several other areas. Across multiple domains, the findings have indicated consistently that the less integral and autonomous one's motivations, the less positive one's adjustment and well-being.

Introjection results in internally controlling regulation, which is not considered part of one's true or integrated self, but instead can be thought of as akin to a false self. Of

course, if the organismic integration process continues to function with respect to an introjected value or process (as, for example, in psychotherapy), that value or regulatory process may, in time, be integrated, but insofar as the integrative process is stalled, introjected regulations remain alien to the self.

Internalization and the Social Context

Although internalization and integration are natural processes, they, like intrinsic motivation and all other all such processes in the organismic dialectic, require nutrients and supports from the social context. We saw in the discussion of intrinsic motivation that this natural activity was organized strongly in terms of the fundamental psychological needs for autonomy and competence. According to self-determination theory, people need to feel competent and autonomous, and when they experience these feelings while engaging in an interesting activity, their intrinsic motivation is maintained or enhanced. However, when they engage social contextual conditions that thwart their efforts toward autonomy and competence, their intrinsic motivation is undermined and they tend to become controlled or amotivated in relation to that activity.

Internalization, which involves accepting attitudes, values, and behaviors endorsed by one's social world, is also theorized to function effectively when people experience autonomy and competence, but there is also a third basic psychological need that, according to SDT, is critical for internalization and integration to operate optimally. Specifically, people have a basic need for relatedness or connectedness with others, and this plays a crucial role in internalization and, as we will see, in healthy development and the prevention of psychopathology. Out of the innate desire to be part of a social matrix, to feel connected to significant others, people tend to internalize the beliefs and behaviors of those others. To the degree that the internalization occurs in the context of autonomy support, the internalized values and behavioral regulations are more likely to become integrated.

Based on the proposition that people have these universal psychological needs, Grolnick and Ryan (1989) proposed that there are three parenting dimensions that are important for facilitating children's basic need satisfaction and thus both their intrinsic motivation and the internalization and eventual integration of extrinsic motivations. These critical contextual (i.e., parenting) dimensions are involvement, structure, and autonomy support.

Parents' being involved with their children, relating to them and providing a moderate amount of consistent, clear structure, facilitates internalization of values and regula-

tory processes, but for those internalized processes to be integrated, the parents must also provide autonomy support. If, instead, parents are excessively controlling, it is likely that any internalized processes will merely be introduced, not integrated.

Being autonomy-supportive for a child implies that one attempts to grasp and acknowledge the child's perspective, use minimal controls to foster behavior, and provide choice when possible. When that occurs, the child will understand the reasons for self-regulating and will feel understood. Further, the behaviors that are encouraged will be performed with a relatively more internal perceived locus of causality. In contrast, being controlling involves parents' pressuring the child to do what they want, emphasizing obedience and compliance.

Most theories of parenting employ a variable that is anchored on one end by a concept essentially equivalent to being controlling. For example, Becker (1964) spoke of restrictive parenting, Schaefer (1959) described controlling parenting, and Baldwin (1955) discussed an autocratic style of parenting. These terms apply to parents who place paramount value on compliance. Children of parents high on these attributes have been found to be hostile (Hoffman, 1960), dysphoric and disaffiliated (Baumrind, 1967), and obedient, low in social interaction, and dominated by peers (Baldwin, 1955).

Although there is general agreement about the controlling end of a parent dimension, there is less agreement about the other end. Whereas some researchers have contrasted control with permissiveness (e.g., Becker, 1964), others have contrasted it with democracy (Baldwin, 1949). We emphasize that autonomy support does not imply permissiveness, neglect, or the absence of action on the part of the parent, but instead conveys an active support of the child's capacity to be self-initiating and autonomous. Of the various concepts that have previously been used in contrast to control, Baldwin's concept of democratic parenting comes closest to autonomy support.

Baumrind (1971) empirically examined the effects of parental styles on internalization. She contrasted authoritative and authoritarian parental styles. The *authoritative* parent communicates openly with the child and encourages independence and individuality, while at the same time holding expectations and standards for mature behavior. The *authoritarian* parent, in contrast, values obedience and compliance and attempts to shape the child according to an absolute standard. Baumrind (1977) found that nursery school girls from authoritarian homes were withdrawn and dependent and boys were aggressive. From our perspective, these two seemingly contrasting behavior patterns are two

sides of a coin, for they are both manifestations of being controlled by authoritarian parents. In one, the child relies excessively on others to control behavior; in the other, the child rebels against the controls and aggresses with little provocation. In contrast, children from authoritative homes were more adaptive in their behavior, displaying assertive, independent, and friendly actions.

Grolnick and Ryan (1989) extended the work of Baumrind and others by proposing a set of three parenting dimensions from which the parenting styles could be derived. The dimensions are autonomy-supportive (versus controlling), structured (versus unstructured), and involved (versus uninvolved). Their dimensionalization recognizes that parental autonomy support can co-occur with parental structure (i.e., consistent and clear expectations, rules, and consequences) or without such structure. Further, any of these parenting styles can be embedded in relationships characterized by various levels of involvement.

Using this three-dimensional model, Grolnick and Ryan (1989) interviewed separately, in their homes, the mothers and fathers of late elementary school students to determine how they deal with their children concerning doing homework and chores. In addition, the children, in their classrooms, completed a self-regulation questionnaire developed by Ryan and Connell (1989), as well as a measure of their understanding of control over school outcomes (Connell, 1985). Teachers rated the children's classroom adjustment and motivation, and school records were accessed to examine objective competence outcomes. Results indicated that parental controllingness predicted children's failure to internalize regulations, as well as poor adjustment and low achievement. Lack of involvement predicted children's not understanding how to control outcomes and contributed to poor adjustment and achievement. Parental inconsistency predicted children's lack of control understanding. Thus, the data indicated that parental autonomy support, structure, and involvement contribute to children's abilities to self-regulate and function effectively in their social contexts. Parents' failure to provide these necessary nutrients leads to poor adjustment and achievement and may set the stage for more profound disturbances.

Grolnick et al. (1991) tested the idea that the effects of the parental environment on children's outcomes are mediated by the children's self-relevant motivations and perceptions. Results indicated that children who perceived their mother and father as less involved and autonomy-supportive also reported poorer self-regulation, perceived competence, and control understanding relative to those who perceived more involvement and autonomy support. These self-relevant motivation variables, in turn, predicted

the children's school performance, thus serving as mediators between the home context and children's performance. Elmen, Mounts, and Steinberg (1989) found comparable results using Baumrind's conceptualization.

Deci et al. (1994) performed a laboratory experiment to explore social contextual influences on internalization and integration. They manipulated three contextual factors that were thought to constitute autonomy support and involvement: a meaningful *rationale* so the individual would understand the personal importance of the requested activity; an *acknowledgment* of the individual's feelings so that he or she would feel understood; and an interpersonal style that emphasizes *choice* and minimizes control. Results revealed that the absence of these three facilitating factors impaired internalization, thus complementing the findings from the Grolnick and Ryan (1989) field study. Further, Deci et al. showed that the internalization that occurred in the conditions not supportive of self-determination (viz., those with at most one of the facilitating factors) was introjected, as reflected by negative relations between subsequent behavior and participants' self-reports of perceived choice, importance of the activity, and enjoyment, whereas the internalization that occurred in the conditions supporting self-determination (viz., those with at least two facilitating factors) was better integrated, as reflected by coherence between subsequent behavior and these affective variables.

The critical difference between introjected and identified motivation, which represent two types of internal motivation, was recently confirmed in an experimental study in preadolescent overweight children (Simons, Vansteenkiste, Braet, & Deci, 2005). Half of the overweight children were encouraged in an autonomy-supportive fashion to follow the guidelines of the four-leaf clover, a simplified version of the food pyramid, by providing them opportunities for choice and self-initiative. In a second condition, children were pressured in a subtle and implicit way to follow the guidelines of the four-leaf clover. The subtle controlling manipulation involved practices of guilt induction ("You might feel guilty for not doing so") and self-esteem contingency ("You might feel better about yourself if you would do so"). The controlling counseling approach no doubt elicited introjects readily available in individuals, while the autonomy-supportive approach was intended to promote identified regulation. Although any effort to follow the guidelines of the four-leaf clover would be initiated by the person in both cases (and not by external forces), the type of internal motivation guiding children's behavior change was of a considerably different sort. Results showed that children in both conditions adopted a more healthy lifestyle during the week following the experimental manipulation. Yet, after 3 weeks, these

gains were maintained only in the condition where an identified regulation was promoted. Children's attendance and weight loss started to decline after two sessions when an introjected regulation was produced, whereas children continued to show up for the diet sessions and lost further weight when an identified regulation was produced.

Similarly, a number of studies speak to the relation between parental autonomy support and internalization. Notably, the model holds up well not only in Western, individualistic cultures where autonomy is a salient value, but also in nations where authority and tradition have predominated. For example, Chirkov and Ryan (2001), in a study of Russian and U.S. high school students' self-reports, found that perceived autonomy support from parents and teachers predicted both more internalized academic motivation and better mental health.

It appears, then, that if the context fails to support self-initiation and choice—that is, if significant others are controlling and uninvolved—people are less likely to internalize values, attitudes, and behaviors than if the significant others are autonomy-supportive and involved. Furthermore, when the context fails to provide the necessary nutriment, internalization that does occur is likely to have the quality of introjection, thus being rigid, conflicted, and marked by negative emotionality.

Weiss and Grolnick (1991) studied the relationship of parental involvement and autonomy support to adolescents' internalizing and externalizing symptoms (Achenbach & Edelbrock, 1987). Adolescents rated their mother and father on dimensions of involvement and autonomy support, and they completed the self-report profile of symptoms. Analyses indicated that parents who were perceived to be *both* highly involved and autonomy-supportive had children who reported very low levels of either internalizing or externalizing symptoms. However, there were significant interactions between perceived parental involvement and autonomy support on both types of symptoms, indicating that the combination of high involvement and low autonomy support yielded a high level of symptoms. It thus appears that feeling close to very controlling parents can be detrimental to a developing child's well-being. This relates as well to the results of Fuhrman and Holmbeck (1995) reported earlier, who showed that emotional autonomy (which we have interpreted as emotional detachment) was more beneficial to teens whose parents were low in support. Having to give up one's autonomy to satisfy the need for relatedness to parents can be quite costly, as can the converse: having to detach to maintain a sense of self.

From these and related studies, we conclude that parental involvement, structure, and autonomy support are

necessary for optimal internalization of social values and regulations and, in turn, for adjustment. It is particularly important to note that parental involvement and structure are not enough, for without autonomy support, whatever internalization occurs is likely to be introjected rather than integrated, and the accompanying tension and inner conflict are likely to be associated with greater symptomatology.

Attachment, Intimacy, and Relatedness across the Life Span: The Role of Autonomy

The connection between autonomy and relatedness has been a hotly debated topic among psychological theorists over the past 2 decades. Some authors (e.g., Gilligan, 1982; Iyengar & Lepper, 1999) see autonomy and relatedness as largely independent if not antithetical, and others (e.g., Bakan, 1966) see them as dialectically related to one another (again implying an original opposition that precedes synthesis). Our view differs from these because we do not view autonomy and relatedness as being in opposition. Indeed, we see them as integral to one another.

When we first began to explore the dynamics of autonomy and relatedness, we assumed that the strength and quality of one's connection to others in a given context could be examined separately from one's sense of autonomy. Accordingly, in a variety of studies, using varied age samples and contexts, we attempted to do independent assessments of participants' feeling related to others and feeling that their autonomy was supported by others. For example, we asked children to rate their parents with regard to both the sense of warmth and connectedness (indices of relatedness) and the sense of their parents' taking their perspective, offering choices, and using minimal controls (indices of autonomy support). Separable factors did not emerge, but instead warmth and connectedness ratings invariantly loaded with those representing autonomy support. Similar difficulties in obtaining independent factors for affection/warmth and autonomy support have occurred for other dyads such as teacher-child and physician-patient. Thus, for example, in studies of classroom climate, it is typically difficult to separate perceived teachers' warmth and caring from their autonomy support. This series of psychometric mishaps strongly conveyed how closely connected one's feelings of attachment and relatedness are to the sense that the other acknowledges and supports one. This has led us to explore these seemingly inextricable constructs more deeply.

With more clarity about the meaning of relatedness, we realized that, phenomenologically, one typically feels authentically related to another person only to the extent that

one feels free to be oneself with him or her (Ryan, 1989, 1991). In other words, one feels warmly related to and secure in one's connection with others only to the extent that there is receptivity to and acceptance of one's real self. Conversely, insofar as there is a felt absence of autonomy support, the quality of relatedness suffers: One's connection is more superficial, insecure, and contingent.

How deep does this connection between autonomy and relatedness run? We suggest that from the very beginning of life, the strength and security of attachment is in part a function of the autonomy support afforded by caregivers. We therefore begin our analysis of these intertwined needs during infancy, and then we proceed to examine this dynamic across the life span.

Autonomy and Relatedness in Infancy

It is particularly difficult to separate the development of autonomy and relatedness in the child's 1st year of life. During this period, according to Stern (1985), establishing a core self is a primary agenda for the infant. Although the self that is consolidated within the first 6 months does not take the form of a conscious representation, it is manifest as coherence and volition. Because infants are highly dependent on caregivers not only for biological necessities such as food and temperature regulation but also for interpersonal necessities such as love, contact, and comfort, these earliest experiences of the self as "initiator" of action occur in the context of very close parent-child relationships in which responsiveness to rising needs and signals of them strengthens the sense of agency and its connections with action.

The interrelated development of autonomy and relatedness is described, albeit using different terms, in attachment theory. According to Bowlby (1969) and later theorists who have elaborated his framework (e.g., Bretherton, 1987), infants are innately prepared to engage in social relations from birth. The nature of these early social relations with primary caregivers shapes the security of attachment and the corresponding working models of self and others that function to organize future social relations.

Perhaps the most emphasized feature in attachment theory that contributes to security of attachment is the caregiver's responsiveness or *sensitivity* (Ainsworth et al., 1978; Brody & Axelrad, 1978). Sensitivity is defined as the provision of contingent, appropriate, and consistent responses to the child's signals and needs (Lamb & Easterbrooks, 1981). Sensitivity is thus a broad concept conveying that caregivers are responsive to the child's initiations in ways that are empathic and appropriate to the child's needs.

We have suggested that one can unpack the broad concept of sensitivity into its component parts and that these parts will correspond to the dimensions of autonomy support, involvement, and structure. Autonomy support is clearly a component of sensitivity in that what one is being sensitive to are the child's initiations, strivings, needs, and developing self. Indeed, Bretherton's (1987, p. 1075) description of sensitivity in terms of "maternal respect for the child's autonomy" captures the essence of such contingent responsiveness. The sensitive caretaker responds to the initiations, cues, concerns, and needs that emerge from the child, and this contingent responsiveness gradually strengthens the child's inner sense of agency and coherence, and thus the meaningfulness of the child's self-initiated action and expression. When responded to, the child experiences a sense of safety and interconnection that is lacking for one whose biddings and expressions have fallen on deaf ears.

Autonomy support is thus a critical component of early relationships, for it facilitates not only the solidity of attachment but also self-development more generally. Numerous studies have supported this perspective by linking sensitivity and/or autonomy support to more curiosity, effectiveness, and ego resiliency (Arend, Gove, & Sroufe, 1979; Grolnick et al., 1984; Waters, Wippman, & Sroufe, 1979), greater self-initiation (Stevenson & Lamb, 1981; Watson, 1966), improved learning (Lewis & Coates, 1980; Yarrow et al., 1975), and in general more resourcefulness and better adjustment (Brody, 1956).

This interrelationship among autonomy support, attachment, and self-development is also considered in Bowlby's (1969) speculations concerning infant exploration and mastery motivation. He postulated the existence of two innate systems that guide the child's behavior and development. The *attachment system* has as its goal the attainment and maintenance of close proximity to and contact with the caregiver; the goal of the *exploratory system* is to discover and master the world around one. These two systems are mutually dependent, however, and the satisfactory attainment of one will occur only in concert with the other. According to Bowlby, to the extent that a child experiences security (i.e., a sense that the caregiver will be accessible and responsive in times of need), the child will feel enabled to venture forth to explore with interest. However, to the extent that attachment is insecure, the child will stay close and monitor the parent's status and thus will not display healthy attempts at mastery and autonomous initiation.

This brief analysis of the role of autonomy and relatedness in infancy suggests the following: Autonomy support is a critical component of caregiving in infancy that shapes

both the experienced quality of relatedness (as reflected in the security of attachment) and the consolidation and vitality of the self (as reflected in both well-being and mastery motivation). Relatedness that is low in autonomy support, by contrast, will set the stage for attachment disturbances and impoverished agency.

Although we have emphasized the centrality of autonomy support to the construct of sensitivity and to formation of secure attachments, it is not the only component variable contributing to these. The sensitive environment also provides involvement and structure. The involved parent dedicates resources to the child in the form of availability, effort, attention, and concrete nurturance. The sensitive caregiver also contributes to security by providing structure in the form of an optimal environment that modulates stimulation in accord with the infant's capacities and state. These contributions to well-being help to provide a sense of safety and comfort that are the backdrops of secure relations and the development of competencies. However, the patterning of additional contributions must grow out of a reading of the child's actual needs and emotional states to facilitate the emerging self. That is, the optimal environment is one that provides resources and introduces structure in a context of autonomy support.

Autonomy and Relatedness during Childhood

As a result of their experiences with early caretakers, children develop a set of models and expectancies regarding interpersonal interaction that are often referred to as object representations (Behrends & Blatt, 1985) or working models (Bretherton, 1991). These internal representations and models are *hypothetical* rather than inductively derived variables, which are used to explain how experiences in relationships with caregivers foster characteristic patterns of interpersonal perceptions and behaviors that an individual exhibits. Because of their hypothetical status, such representations have been assessed and described in many different ways. Indeed, the methodological and content focus of representational assessments is as varied as the theoretical models that have been brought to bear on early childhood relatedness.

Given the emphasis in self-determination theory on the connections between relatedness and autonomy throughout development, one particularly intriguing conceptualization of object representations is that based on the *mutuality of autonomy* construct. Derived from object relational (Winnicott, 1960/1965) and self psychological (Kohut, 1971) theories, this construct assesses one's internalized schemata of relationships along a dimension ranging from those characterized by reciprocal dialogue and autonomy to

those characterized by unifocal power and overwhelming control. Thus, the construct inherently assumes that the quality of one's relatedness is to a great degree a function of the autonomy supportiveness that characterizes it.

In a study of urban preadolescents, Ryan, Avery, and Grolnick (1985) employed a projective measure of mutuality of autonomy developed by Urist (1977). Based on the idea that experiences of relatedness that lack autonomy would be associated with less integrated functioning, these investigators hypothesized and found that poorer mutuality of autonomy predicted lower perceived control, poorer school grades, and, most important, worse interpersonal and classroom adjustment as rated by teachers. Tuber (1992) recently reviewed a number of studies with clinical samples that further document how various forms of psychopathology in childhood and adolescence are typically accompanied by lower levels of mutuality of autonomy.

Avery and Ryan (1988), also working with urban children in middle childhood, utilized a different projective assessment of object representations developed by Blatt, Chevron, Quinlan, and Wein (1981) to examine the parental antecedents of the quality of children's object representations. Avery and Ryan found that two variables derived from self-determination theory, perceived parental autonomy support and involvement, predicted the overall nurturant quality of parental representations. Further, a wide array of functional outcomes, including peer sociometric ratings, general adjustment ratings, and perceived social and cognitive competence, were facilitated by parental autonomy support and involvement. As in infant attachment, these results bespeak the critical components of autonomy support and involvement underlying secure relatedness.

There is evidence that parents' involvement and autonomy support facilitate children's adjustment at key transition points. The transition from elementary school to junior high is a time of vulnerability, with many children experiencing declines in perceptions of competence and control and school grades. Grolnick, Kurowski, Dunlap, and Hevey (2000) examined levels of involvement and autonomy support in parents of children making this transition both before and after the move to junior high. These authors showed that high levels of involvement during sixth grade buffered children from experiencing declines in perceived competence and grades over the transition. Children of parents who displayed high levels of autonomy in sixth grade and those of parents who increased or maintained their levels of autonomy support and involvement over the transition did not display the same increases in acting-out and learning problems as those of parents who were low in autonomy support or decreased their provision of resources

across the transition. The idea that involvement is no longer necessary when children reach preadolescence is inconsistent with these data, which illustrate the ongoing importance of involved, autonomy-supportive parenting.

Autonomy and Relatedness in Middle and Late Adolescence

Adolescence, as we already discussed, is a critical period of life in which the teenager is rapidly developing capacities for independence, while still needing considerable support and nurturance and, we argue, a secure base of attachment. Considerable evidence suggests, however, that the security of attachment in this age is quite dependent on caregiver's support for autonomy.

First, several studies support our view of adolescents' continued need to feel secure relatedness to parents. For example, Ryan, Stiller, and Lynch (1994) investigated the contributions of relatedness to parents, teachers, and friends to the prediction of motivation, adjustment, and self-esteem of early adolescents. They found that the quality of relatedness to parents and teachers, assessed in terms of felt security, as well as utilization and emulation of these target figures, predicted adjustment, again attesting to the facilitating effect of relatedness on one's integration and well-being. Further, they found evidence that the quality of relatedness to parents predicted the quality of relatedness to both teachers and peers and appeared to have priority among working models. Similarly, Bober and Grolnick (1995) assessed adolescents' felt security with and emulation of parents and peers. Adolescents who displayed internalizing symptomatology reported low levels of felt security with parents and peers yet emulated these groups. Adolescents who displayed externalizing symptomatology reported low levels of both felt security and emulation of parents.

Ryan and Kuczkowski (1994) also examined the effects of felt security on the development of autonomy in adolescence. In a cross-sectional design, they assessed adolescents' experience of private audiences (Elkind, 1967), arguing that the private audience phenomenon, a precipitate of cognitive development in early adolescence, typically represents a heteronomous influence on adolescent behavior (Elkind, 1967; Piaget, 1965). This phenomenon is essentially akin to public self-consciousness and can be the basis of internally controlling regulation, particularly if it persists past early adolescence. Ryan and Kuczkowski supported this reasoning by showing that the salience of private audiences to adolescents was negatively related to public individuation. Further, based on theorizing by Lapsley and Rice (1988), Ryan and Kuczkowski predicted and

found that whereas security of relatedness to parents was unrelated to the strength of private audiences in early adolescence (when it is an emerging and normative aspect of ego development), it was more strongly related in later adolescence. Those adolescents experiencing emotional insecurity with parents tended to remain more preoccupied with private audiences and were less capable of public individuation, in opposition to normative trends. This shows one specific way in which the growth of autonomy is dependent on one's embeddedness in secure relationships.

Ryan and Lynch (1989), in a study reviewed earlier in this chapter, examined both theoretically and empirically the issues of autonomy and attachment in early, middle, and late adolescent samples. They cited several theorists and researchers who have viewed adolescents' development of autonomy in terms of an increasing independence and non-reliance on parents. Ryan and Lynch, in contrast, argued that autonomy is more typically *facilitated* by attachment and dependence on parents rather than by detachment. Indeed, they suggested that among the primary reasons that adolescents detach from and refuse to rely on parents is that parents have been overly controlling and/or underinvolved. According to Ryan and Lynch, adolescents whose parents provide a more optimal caretaking environment in which there is both involvement and autonomy support do not need to relinquish their attachment in order to become more autonomous and self-regulated. Rather than having to trade off relatedness for autonomy, such adolescents can maintain both, precisely because in an autonomy-supportive context the parent-adolescent relationship itself changes in accord with developing adolescent capacities and needs. In support of their perspective, Ryan and Lynch showed that adolescents with stronger positive ties to parents were, in fact, better adjusted and self-regulated than were those whose connectedness with parents was poorer. This fits with a number of other extant perspectives and findings (e.g., Behrends & Blatt, 1985; Hill & Holmbeck, 1986; Kandel & Lesser, 1969).

T. Kasser, Ryan, Zax, and Sameroff (1995) investigated a racially and economically diverse sample of teenagers and their mothers in a study of the developmental antecedents of extrinsic aspirations for wealth, relative to intrinsic aspirations such as growth, relatedness, and community. The adolescents' perceptions of the degree to which their mother was democratic, noncontrolling, and warm were collected, as were the mothers' self-reports on these same variables. In addition, clinical interviewers made their own ratings of maternal nurturance based on a previously recorded maternal narrative. Low scores on

these dimensions, of course, represent the types of social environments that thwart satisfaction of the children's basic psychological needs for autonomy and relatedness. Kasser et al. found that when mothers were low on democracy, noncontrollingness, and warmth, as indexed by any of the three rating sources, the adolescents placed significantly higher relative importance on the extrinsic aspiration for wealth. The results thus suggest that parenting environments that thwart children's need satisfaction facilitate the development of extrinsic aspirations such as wealth that are visible indicators of "worth" and may represent substitutes for basic need satisfaction. Kasser et al. also examined archival data from the mothers of these teenagers that had been collected several years earlier. A variable labeled risk, derived from ratings by trained observers, represented mothers' coldness in interactions with their children and controllingness in parenting beliefs. This risk index significantly predicted higher relative extrinsic aspirations in the teenagers. Moreover, analyses of well-being indicators showed that teens holding extrinsic values were less well adjusted and were less constructively involved in their community. These analyses provide initial support for our developmental speculations that psychological need deprivation can foster "need substitutes" or compensatory motives such as overly strong extrinsic aspirations.

One ramification of the development of strong compensatory motives such as extrinsic aspirations that result from lack of support for autonomy and relatedness is that they tend to perpetuate the lack of need satisfaction. Extrinsic goals keep people focused on the need substitutes and thereby exacerbate the negative consequences for well-being by leading them away from a focus on relationships and growth (see T. Kasser, 2002, for a more extensive discussion of this issue).

Autonomy and Relatedness in Young Adulthood

According to Reis and Shaver (1988), intimate relationships in adulthood not only depend on strong ties, but they also entail an acceptance and encouragement of the true self of one's partner. This affordance of autonomy support breeds a sense of trust and confidence, as well as facilitating self-expression and actualization. Several studies support this critical point concerning wellness and full functioning in adulthood.

Dresner and Grolnick (1992) examined how the autonomy and interpersonal relatedness of college women was influenced by their parental object representations. The women's current relationships were classified as being car-

ing, respectful, and intimate, or alternatively, as being either superficial or enmeshed (Levitz-Jones & Orlofsky, 1985; Orlofsky, Marcia, & Lesser, 1973). Results indicated that whereas women whose relationships were caring and intimate had parental representations that were accepting and autonomy-supportive, the women with more superficial relationships had object representations that were nonaccepting and overcontrolling, and the women with enmeshed relationships had representations that were nonaccepting but idealized. Further, women who were high in autonomy orientation (Deci & Ryan, 1985a) had parental representations that were autonomy-supportive, whereas those who did not display high autonomy had representations that were saliently controlling.

La Guardia, Ryan, Couchman, and Deci (2000) studied patterns of secure and insecure attachment in multiple social partners of college student participants, most of whom were young adults. The focus was especially on within-person variations in security of attachment. La Guardia et al. acknowledged that individual differences in security of attachment (also referred to as between-person security of attachment) are likely to be a significant predictor of security of attachment in later life with other individuals, such as best friends and romantic partners. However, they suggested that there is likely to be a significant amount of variance in a person's security of attachment with each partner, which is a function of what goes on in that particular relationship. More specifically, just as primary caregivers' supporting the autonomy, competence, and relatedness of children affect their children's attachment security with them (and their children's working models), the support for adults' autonomy, competence, and relatedness provided by relational partners will affect the person's security of attachment with that partner. Thus, security of attachment was hypothesized by La Guardia et al. to be a function both of between-person factors (i.e., individual differences) and of within-person factors (i.e., the need satisfaction provided by the particular partner). In three studies, these researchers examined the security of attachment that college students have with their mother, father, romantic partner, and best friend, as well as the level of satisfaction of the needs for autonomy, competence, and relatedness they experience in each of those relationships. Further, they assessed several mental health indices. Using multilevel modeling, the results showed that there was a significant amount of variance in attachment security at the between-person level, thus confirming that attachment security is to some extent an individual difference. However, considerably more than half the variance in attachment security was

at the within-person level, indicating that people's security of attachment differed substantially from partner to partner. Then the researchers examined whether the within-person variability in attachment security could be systematically explained by need satisfaction. In each study, they found that need satisfaction with a relational partner did in fact account for significant variance in attachment security with that partner. Subsequently, they examined satisfaction of each need separately, and they found that feeling autonomous in a relationship was an important predictor of attachment security for that relationship; similarly, feeling competent in a relationship was a weaker though still meaningful predictor of felt attachment. In other words, the degree to which a person experienced satisfaction of each of the three basic psychological needs with an attachment partner affected the degree to which the person was securely attached to that partner. Finally, at the between-person level, both need satisfaction and attachment security predicted psychological health, and, at the within-person level, both need satisfaction and attachment security predicted relationship satisfaction and willingness to rely on the relational partner.

To summarize, the La Guardia et al. (2000) study indicated that satisfaction needs for autonomy, competence, and relatedness in adult attachment relationships predicted security of attachment, relationship quality, and emotional reliance in that relationship. Not only is need satisfaction important for attachment security and relationship satisfaction of children with their parents, but it is similarly important for attachment security and relationship satisfaction within adult relationships.

A study by Deci et al. (2004) examined mutuality of autonomy support in college-age close friends as it predicted satisfaction of the basic psychological needs, security of attachment, emotional reliance on the friend, and indicators of well-being. They assessed the degree to which each relational partner received autonomy support from the friend and the degree to which he or she gave autonomy support to the friend. Results suggested that both receiving and giving autonomy support were related to relationship quality and well-being, and that this was so for female-female pairs as well as male-male pairs. In other words, this study provided another set of data indicating that autonomy is important for females just as it is for males. When a person's receiving and giving autonomy support competed for variance in the relationship quality, both receiving and giving autonomy support contributed independent prediction. Further, when they competed for variance in well-being, giving autonomy support to one's partner was even more

important than receiving it. In other words, in peer relationships such as close friendships, mutuality of autonomy support—giving it as well as getting it—was shown to be important for people's psychological well-being.

Old Age: The Continuing Need for Autonomy in Relationships

Increasingly, the issue of autonomy has been understood as equally important in older persons as it is among younger ones (e.g., Langer & Rodin, 1976; O'Connor & Vallerand, 1994). From a developmental perspective, old age brings with it some degree of increasing dependency on others (Baltes & Silverberg, 1994), and thus it catalyzes dynamic interactions in which the needed supports must be willingly accepted, while not controllingly imposed, for optimal adjustment (Ryan & La Guardia, 2000). In this context, the issue of autonomy support plays a central role in determining the quality of one's relationships.

In one such study, V. G. Kasser and Ryan (1999) examined this dynamic picture in the context of a care facility for the elderly where the issue of dependency was salient. They found that the health and vitality of persons under care were significantly related to both the perceived quality, rather than amount, of relationship support and moreover, that autonomy support from others played a critical role. Satisfaction of the need for autonomy was associated with lower depression, higher vitality, more life satisfaction, and higher levels of positive well-being.

In another study, Langer and Rodin (1976) did an intervention among institutional elderly participants in which some were given greater choice and personal responsibility about aspects of their life in the institution, while others were taken care of by staff members who made decisions for them. Those residents who were encouraged to take greater initiative and make choices displayed better psychological and physical health than those who were cared for well but not encouraged to be self-initiating.

Summation

The most general point to be derived from all these studies, which span the period from infancy to old age, is that relatedness and autonomy, rather than being opposing or antithetical variables, function in a complementary, synergistic manner with respect to personality integration. People who are provided with an atmosphere of autonomy support and involvement (i.e., dedication of resources) are likely to experience both greater security of attachment and a greater sense of personal autonomy. In the context of autonomy-supportive relationships, one has the circumstances conducive of agency and mental health. It is worth noting,

however, that social contexts can, of course, turn satisfaction of the fundamental needs for relatedness and autonomy against each other. In other words, although satisfaction of the two needs is inherently synergistic, they can be made antagonistic toward each other by the social context. For example, when parents make love for their children contingent on the children's doing what the parents insist that they do, the parents are essentially requiring the children to give up autonomy to receive relatedness. As expected, research has shown that when parents use this type of conditional regard as a socializing strategy, children pay substantial intrapsychic and interpersonal costs (Assor et al., 2004). Indeed, these findings provide further evidence of the importance of experiencing satisfaction of both the need for autonomy and the need for relatedness.

EMOTIONAL REGULATION

Central to the definition of well-being is the capacity to regulate and integrate emotional experiences (La Guardia & Ryff, 2003; Ryan & Deci, 2001). Equally clear, deficits in the regulation of emotion and the inability to use emotions to appropriately guide behavior are cardinal features of most forms of mental illness. Accordingly, along with examining the developmental processes of intrinsic motivation, internalization, and social relatedness, we turn now to the critical topic of emotional regulation, a topic that is deeply intertwined with the issue of autonomy and its support in social contexts.

In any discussion of autonomy in relation to emotional regulation and integration, we must begin with an acknowledgment of the complexity of emotions and the multiple dimensions that impact their regulation and expression (see Cacioppo, Bernston, Sheridan, & McClintock, 2000). In particular, there are salient individual differences in people's tendencies to experience emotions (e.g., Gable, Reis, & Elliot, 2000) based on both genetic factors and their interactions with early environmental events. Individual difference factors make the problem of emotional regulation and integration much more formidable for some persons, whose sensitivity or deficits in sensitivity make the challenges of accessing, modulating, expressing, and using emotions highly challenging. This is much of what clinicians like ourselves deal with on a daily basis, and it is an issue that interventions from the psychotherapeutic to the pharmacological attempt to address.

This section is not intended to detail the nature of these individual differences in genetics and their expressions in phenotypes. Nonetheless, we believe that any reasonable

summary of that complex literature makes clear that, regardless of genetic inputs, there is a significant, albeit interactive, role played by social environments in fostering healthy or unhealthy regulatory styles. This is our particular focus, as our interest throughout this chapter is in understanding the ways social, cultural, and psychological factors affect development and foster wellness versus pathology.

To more concretely understand what it is about social environments that constructively foster versus debilitate a growing person's capacities for emotional awareness and regulation, it is important to have a clear conception of what healthy emotion regulation is and to specify what features of social contexts can facilitate it. We thus begin with a theoretically based conceptualization of healthy emotional regulation based on a eudaemonic rather than hedonic view of wellness (Ryan & Deci, 2001). Specifically, in our view, the state of wellness is not, as some would hold, the presence of positive emotions and the absence of negative ones (see Kahneman, Diener, & Schwartz, 1999, for such a hedonic view). Indeed, our position differs strongly from this. Instead, our model suggests that emotions are *informational* inputs essential to guiding action and growth (Deci & Ryan, 1985b). There are not good or bad emotions because all emotions provide organismically valuable guidance (Deci & Ryan, 2000; Parrott, 1993). A similar view is expressed by Levenson (1999), who suggested that emotions provide organisms with a built-in feedback system—a cascade of cognitive, motivational, and physiological activities—that signals us to evaluate our environment and act in accord with that evaluation. Instead of the hedonic view, then, we view wellness in terms of a person's being fully functioning—being able to exercise potentials, connect with others, find meaning, and experience vitality. A eudaemonic view of wellness suggests rich access to positive and negative feelings, a capacity to express them, and the ability to use them to inform one's behaviors and goals toward the satisfaction of basic psychological needs. This in turn supports personal growth, self-acceptance, and abilities to intimately connect with others. We label such eudaemonically oriented regulation of affect emotional integration.

Emotional Integration: A Theoretical View

Whereas emotional regulation per se refers to the capacity to modulate or manage one's emotions and impulses, *emotional integration* refers to the most autonomous form of emotional regulation. Specifically, emotional integration involves a differentiated awareness of one's emotional states and the capacity to use this sensitivity and awareness

in the volitional regulation of action. In our view, then, autonomous functioning is dependent on emotional integration, because emotions, when they are mindfully perceived, supply essential information that guides one toward the fulfillment of psychological needs and toward the regulation of behavior in the direction of growth and wellness.

From our perspective, healthy emotional integration is characterized by an allowing of and interest in inner experience, rather than the control or stifling of emotion. In contrast to integrated regulation, internally controlling regulation, which involves blocking or suppressing emotions, not only is nonoptimal but, as we will see, is implicated in various forms of psychopathology and ill-being. Of course, emotional integration presupposes regulatory capacities in that being able to choicefully use emotional experiences requires that an individual not be overwhelmed by the experiences, which would result in dysregulation and impulsivity.

In the developmental and child clinical literatures, there has been a great deal written under the broad rubric of emotion regulation, referring to the management or control of affect (e.g., Garber & Dodge, 1991). Much extant work implicitly embraces reduction in negative emotions as the criterion for effective regulation, although there is increasing recognition that the capacity to initiate, increase, and maintain positive emotions is also important (Fredrickson, 2001; Gross & John, 2002). We argue, however, that there is more to optimal regulation than downward modulation of the negative and upward modulation of the positive in the experience and expression of emotions.

At the same time, emotions can be experienced as more than just signals or informational inputs. Indeed, emotions can feel controlling, as when they overwhelm autonomous self-regulation or automatically drive action. Even the etymology of the term emotion conveys this idea of a force that propels motion. Alternatively, emotions can be overcontrolled, so that one loses access to them, and in such cases they can fail to move us when they should. A woman who chronically suppresses her anger at others and distorts it into self-disparagement is therefore disabled in terms of managing the sources of distress in her life, even as she appears to be controlling her anger. Accordingly, any conception of healthy or integrated emotional regulation is based neither on emotions controlling people nor on people controlling their emotions. Between being controlled by emotional presses and controlling them is a third term, namely, the self. When the self can access feelings without being controlled by them, the opportunity for autonomous self-regulation is maximized. This, of course, is something that develops over time.

Developing Emotional Regulation

The development of capacities to regulate and integrate emotions in more flexible and autonomous ways was explored in studies of 12- to 32-month-old children by Grolnick, Bridges, and Connell (1996). This team of investigators observed toddlers in two sets of mildly stressful situations: waiting to play with an attractive toy (or to eat a food) and a brief separation from mother. The child's emotionality (i.e., level of upset) and strategies to regulate this upset were then coded. Results supported an autonomy continuum in that the more autonomous (i.e., proactive) strategies were associated with the least upset, whereas the least autonomous (i.e., the more controlled or passive) strategies were associated with the most upset. Further, there were increases with age in the use of more active strategies, indicating development of emotion regulation through the toddler years. Finally, relations between use of particular strategies and emotions became more consistent with age, as did use of the same strategies across situations, indicating a more coherent emotion regulation system over development.

This evidence is consistent with the idea that, as children move beyond the 1st year, they must increasingly acquire the capacity to voluntarily control impulses and emotional expressions. Vaughn, Kopp, and Krakow (1984), for example, found a linear increase in children's ability to control urges and delay gratification over the period from 18 to 30 months. The failure to develop this and related regulatory capacities, of course, is likely to result in maladaptive behaviors and thoughts, such as aggressive acting out (Dodge, 1991) and having more depressive ideation and self-deprecating expectancies (Garber, Braafladt, & Zeman, 1991).

As noted, the regulation of emotions and impulses is not just a matter of controlling oneself. Some children in a negatively arousing situation, such as being asked to delay gratification, will exert great effort, forcing themselves to push emotions out of their minds. But controlling themselves in this way requires attention and energy and can diminish the capacity for adaptive engagement with the environment. When used as a chronic way to deal with distress, it leads children to experience being controlled by their own harsh thoughts and to display nonadaptive engagement. In contrast, other children in the same stressful settings may be more flexible (i.e., less rigid and pressured) in dealing with the situation, for example by doing alternative activities or talking about their disappointment, signifying that they have developed more adaptive capacities for self-regulation of emotion.

Adaptive modes of self-regulating emotions thus entail gradual movement from reliance on mediation by others for modulation of one's inner forces to reliance on one's own inner resources (Cicchetti, Ganiban, & Barnett, 1991). But increasing self-reliance in coping with emotions does not ensure true emotional self-regulation, for the latter requires being able to flexibly use inner experiences to adaptively interact with the environment.

Block and Block (1980) characterized ego resiliency in terms of a balance between overcontrol and undercontrol, thus conveying that neither dysregulation nor being rigidly regulated is an optimal outcome in developing self-regulation of emotions. Kopp (1982) made a similar distinction between self-control, which is the ability to inhibit behavior in the face of external demands, and self-regulation, which involves a greater capacity for adapting to new situations. From Kopp's viewpoint, self-control and self-regulation are sequential stages of early childhood development, whereas we propose that the rigid versus flexible forms of regulation represent markers on a developmental continuum of autonomous regulation that is relevant throughout life. This movement toward autonomous regulation of emotions and impulses, as noted, is considered a natural aspect of the development of self (Deci & Ryan, 2000; Ryan, 1993).

Deci and Ryan (1985b) drew from Greenspan (1979) in referring to the development of regulatory processes for autonomously managing one's emotions as "integration at the internal boundary" (i.e., the boundary between the self and other aspects of the person). This was contrasted with the development of regulatory processes for engaging in activities deemed important by the social world as "integration at the external boundary" (i.e., the boundary between oneself and the world). Although these two developmental functions, referred to, respectively, as the development of emotion regulation and internalization, are somewhat different, they are similar in many respects. Both involve gaining the capacities to regulate oneself with respect to behavior that is not intrinsically motivated, and both entail a developmental progression in which the child gradually relies less on cues and structures from the social context and more on internal cues and structures. The development of emotional self-regulation can thus be conceptualized as movement from reliance on outside sources to identify, modulate, and regulate affect, toward a growing capacity for autonomous, flexible, and adaptive regulation (Grolnick Weiss, McKenzie, & Wrightman, 1996).

Yet, this developing capacity for emotional regulation is not just a function of time and maturation. In fact, in our

view, it is very much an *interpersonal* process. It is in the interpersonal realm that we originally experience emotions as being regulated by caregivers, more or less responsively and effectively. These originally interpersonal regulations then become internalized as regulatory styles. Thus, critical to our position is the interplay between an autonomy-supportive social context that affords access to and expression of emotional experience, and a supportive guidance of that process toward behavioral regulation (Grolnick, Bridges, et al., 1996; Gross, 1999). In other words, responses of significant others are critical to avoiding either the Scylla of dysregulation or the Charybdis of overcontrol.

Mature Emotional Integration

The process of increasingly integrating one's emotions and regulatory capacities is merely a continuation of the work a child does in gaining regulatory capacities with respect to emotions, but it represents a mature version of that process. Whereas emotional regulation is concerned with the modulation of emotional experience and expression, emotional integration is concerned specifically with the degree of flexibility and choice one feels in the regulation of emotions and emotion-related actions. To the extent that one's emotions and regulatory capacities are integrated aspects of the self, one is able to take interest in them and experience them as inputs to autonomous actions. In contrast, if regulatory capacities are merely introjected and thus in conflict with the emotions, a person is likely to suppress the feelings and ignore their personal meaning.

We have suggested that a healthy emotional life requires awareness of feelings—regardless of their valence—and support within the environment to promote fullness of experience and emotional expression. Simply put, when people can authentically engage their emotional life in the context of supportive relationships, they can manage the excitements and challenges offered and engage their emotional world more fully. It is in this interpersonal/social space that people will flourish, at both the psychological and physical level, and will be able to more effectively combat life's stresses at either of these levels.

Emotional integration as herein viewed concerns the degree to which emotions can be assimilated and utilized by the self. It is important to contrast this view of integration with the conception of integration as the synchrony among affective, behavioral, and cognitive systems (Greenberg, Kusche, & Speltz, 1991). In part, synchrony has been equated with integration based on the fact that quite often, synchrony represents the congruence among action, feel-

ings, and consciousness and thus can be a *sign* that emotions have been fully acknowledged and freely expressed and that the behaviors associated with them are integrated and endorsed. But coordination among behaviors, affects, and cognitions (i.e., the fact of synchrony) does not guarantee integration of these processes into the self. Emotional expression and actions related to it can often be characterized by highly correlated systems, yet still can have an external perceived locus of causality. Conversely, one can have affects that one is fully aware of but that one meaningfully chooses not to express behaviorally in a certain context. Such apparent disynchrony can represent a high degree of integration in our current use of that term. Integration to the self and synchrony are thus not the same thing, the crucial issue being the degree to which emotions and regulatory processes have come into harmonious relations with other aspects of the integrated self.

Koestner et al. (1992) explored the relation of autonomy to the integration and synchrony of emotions, cognitions, and behavior. They separated participants into an autonomy-oriented group and a control-oriented group based on a measure developed by Deci and Ryan (1985a) and then explored the consistency of behavior, attitudes, and traits between these two groups. Their general hypothesis was that autonomous participants, because they are more integrated, would evidence greater consistency across these aspects of personality than would controlled participants, who are theorized to be more rigid and fractionated. In the first two experiments presented, the researchers found very high correlations between the behavioral and self-report measures of intrinsic motivation in the autonomous groups, but no correlations in the controlled groups. The autonomy-oriented participants displayed greater congruence between behaviors and feelings than did controlled participants. In another study, Koestner et al. had participants complete a trait measure of conscientiousness, and then they gave them an opportunity to behave conscientiously in the succeeding days. Participants' conscientiousness scores and their conscientious behavior were significantly more highly correlated in the autonomous group than in the controlled group. Finally, a friend of each participant rated him or her on various traits, including conscientiousness, and the self-ratings and peer ratings were also more highly correlated for the autonomy-oriented participants than for the control-oriented participants. Taken together, this set of studies provides support for the theoretical proposition that autonomy is associated with greater congruence among traits, behaviors, and feelings, which we interpret as a reflection of greater integration in personality.

Facilitating or Undermining Emotional Integration: The Role of Autonomy Support

Having articulated the characteristics that define emotional integration, our second interest is in how social environments can enhance or undermine capacities for both regulation and integration of emotional experiences. The importance of the social/interpersonal context is apparent in infancy and childhood (particularly in regard to relationships with caregivers) and continues in relationships throughout life (Reis & Shaver, 1988). Our focus on autonomy support thus homes in on what we believe to be a critical social contextual resource in emotional development.

Emotional Regulation and Caregiving in Early Development

Many theorists view the development of self-regulation of inner impulses and affects as beginning at birth and involving homeostasis as a neurologically based function. Greenspan (1979), for example, described infants during the early weeks of life as being centrally concerned with inner equilibrium. The signals a child sends when experiencing disequilibrium alert caregivers to respond in ways intended to allow the child's return to equilibrium. As Emde (1983) suggested, this initial regulation through caregiver mediation is the basis on which the child gradually learns to monitor and manage his or her own equilibrium.

For this learning to occur, caregivers need to be emotionally responsive and to have effective strategies for initiating, maintaining, and modulating their emotionality (Grolnick & Bridges, 1992). Before addressing that issue, however, it is important to emphasize that the creation of effective regulatory strategies is not solely a function of the caretaking environment, for the child's temperamental qualities may intensify particular emotional states and influence the sequential flow of those states (Lewis & Michalson, 1983). Temperamental factors, which are relatively stable tendencies with biological underpinnings (Goldsmith et al., 1987), may include soothability and irritability (Brazelton, 1973), sociability, adaptability, and difficulty (Thomas, Chess, & Birch, 1968), and reactivity and self-regulation (Rothbart & Derryberry, 1981). Such factors play a significant role in the development of emotional self-regulation, although we view these individual differences in temperament as aspects of the child's "starting point" that interact with the caretaking environment as he or she develops emotional self-regulation. Temperament thus influences how formidable a task the development of emotional self-regulation will be for a child, and as with all

developmental processes, the magnitude of the challenge faced by different children can be quite different.

The challenge faced by children with difficult temperaments can also be exacerbated because their temperament and emotional expressiveness affect the socializing environments, which in turn further affect the children. Children who are irritable and not very soothable may influence their caretakers in ways that make them less nurturing and supportive. As Dix (1991) pointed out, children's behavior can stimulate emotions in parents that undermine their effectiveness and responsiveness, thus making it even more difficult for the children to develop personal autonomy and interpersonal relatedness.

Holding Environments as Autonomy-Supportive

Winnicott (1960/1965) described the "holding environment" as one in which the infant's impulses, affects, and frustrations are satisfied by the parent before they become overwhelming, and in which the parent is sensitive to the cues and initiations of the infant. For Winnicott, a responsive holding environment facilitates the infant's developing sense of agency and vitality, although the dynamics of such responsiveness are complex and subtle. For example, when impulses and affects are experienced in the presence of a caregiver who is sensitive to what the child can tolerate, the caregiver will hold and soothe the child when that limit has been reached, and the borders of the child's self experience will be broadened. The child will learn more about his or her own inner world and its relation to the social context; the child will experience both the force of the urges and the nature of gratification. In contrast, to the extent that the child is left alone with strong, unsatisfied urges, the child may either suppress them because they are so threatening or be overwhelmed by them, ending up disoriented. The experience of being responded to and thus, in a sense, regulated by an empathic other is therefore crucial to the child's developing the capacities for regulating himself or herself.

Brazelton, Koslowski, and Main (1974) similarly emphasized the importance of the parents' ability to attend to infants' cues and to appreciate their need to withdraw from stimulation following periods of intense interaction. Sensitive parents recognize their infants' attempts to elicit interaction, but equally important, they respect the infants' need to be without stimulation. Such parents adjust their own rhythm and behavior to that of their infants.

Greenspan's (1981) notion of a growth-promoting early environment emphasizes the capacity of the environment to balance the infant's need to engage the world and to experi-

ence self-regulation or homeostasis with respect to inner states. In a growth-promoting environment, the parent is available, providing soothing and comforting to supplement the child's emerging capacities to modulate inner states. The parent also provides stimulation and opportunities to engage the environment at times when the child is alert and ready. In the growth-inhibiting environment, the parent may be unavailable to provide comfort and regulatory help such that the child does not experience comfort and harmony. Without self-regulatory help, the child will need to shut out external stimulation, and engagement of the environment will be undermined.

In a study of normal mother-infant interactions, Field (1987) found that the mother adjusts her behavior to her infant's to provide adequate stimulation and arousal modulation. In an optimal interaction, the mother's and infant's attention and affective behavior are synchronized. If, however, the mother is emotionally unavailable or unresponsive, as in the case of depressed mothers (Tronick & Gianino, 1986), the relationship will be asynchronous and the child will be likely to experience disorganization and to manifest disturbed state regulation. Field, Healy, Goldstein, and Guthertz (1990) in fact found more negative affect and greater asynchrony between mood states in depressed mother-child dyads than in normals. The experiences of regulation and dysregulation in the mother-child dyad thus affect the child's developing the capacity for self-regulation.

In a study of emotional regulation (Shields, Cicchetti, & Ryan, 1994), maltreated children and comparison children were observed on the playground interacting with other children. Behaviors were coded for appropriate and inappropriate instances of positive and negative affect. Maltreated children displayed poorer emotional regulation than matched controls. Presumably, experiences in the family rendered the maltreated children deficient in the processes necessary to deal adaptively with stressful experiences. These children, who were less effective at emotion regulation, also displayed less social competence, emphasizing the adaptive importance of self-regulatory capacities.

This research and theory is consistent with the model of optimal caregiving presented by Grolnick and Ryan (1989) in which involvement, autonomy support, and structure are considered essential for children to self-regulate emotion. Parental involvement helps child maintain a tolerable level of distress so they are not overwhelmed by and can learn to manage the inner forces of emotion. Parents' autonomy support helps the children to build confidence in their abilities to autonomously initiate and maintain regulatory

strategies by allowing the children to struggle with distressing situations while letting them know that the parents are available if needed. And parents providing structure in the form of consistency, developmentally appropriate challenges, and limit setting allows the child to trust and take interest in the environment and in his or her affective relation to it.

In support of this framework, there is evidence that children display more adaptive regulatory strategies when their parents are available and involved (Bronson, 2000). However, beyond the importance of availability is the necessity of opportunities for the children to be autonomous. The concept of autonomy support is a complex one (Grolnick, 2002; Reeve, 2002). It entails accepting and nurturing children and relating to them from their perspective. When parents are accepting of the children, understanding what is going on from the children's perspective, it sets the stage for the children's self-acceptance, and this is particularly true with regard to emotions. Further, being accepting of and responsive to the children's emotional initiations, as with any type of initiation, supports and strengthens the children's sense of agency and autonomy and their definition of self as an initiating being. In contrast, when parents fail to respond to their children's emotional expressions or when they react negatively to the emotions, it is likely that the children will internalize those responses, which will become the basis of the children's failing to accept the emotions in themselves.

Calkins (1997) and Calkins and Johnson (1998) found that mothers' use of positive guidance (akin to autonomy support) was associated with greater use of distraction and constructive coping in emotion-inducing situations. On the other hand, children of mothers who used high levels of negative control during free play spent more time orienting to a desired but forbidden stimulus. They used less self-distraction and were less physiologically regulated during a waiting situation relative to children of mothers who used less negative control.

Grolnick, Kurowski, McMenamy, Rivkin, and Bridges (1998) also examined the strategies mothers use to help their young children regulate distress. Children of mothers who maintained their active assistance beyond what the children needed were less able to regulate their distress when on their own. Thus, although responsiveness to distress is important, parents who took responsibility for regulating children's distress and did not allow the children opportunities to self-regulate appeared to undermine children's self-regulatory capacities. Because the capacity to effectively modulate distress is so integral to mental health

and the prevention of psychopathology, an environment supporting this capacity is of crucial importance.

Allowing and encouraging the adaptive use of emotions and responding to and supporting them is certainly important, but parents also need to set appropriate limits on behavior while allowing adequate expression of feelings (see Koestner et al., 1984). This facilitates the child's attunement to the social world and acceptance of self in the process of adapting to it. Children can thus learn to be respectful of others—or, as Angyal (1965) put it, to assume a homonomous attitude—while seeking their own gratification and expression. Developing the capacities for respecting others and delaying gratification represents a central agenda for the person from toddlerhood through adulthood; it involves learning when and how it is reasonable and appropriate to express one's feelings and being able to use that information in a way that enhances the autonomous regulation of behavior. Thus, emotional regulation entails internalizing values and regulatory structures provided by caregivers, a process that functions much like the internalization of any other behavioral regulation.

AUTONOMY DISTURBANCES

As the development of self proceeds optimally in social contexts where children experience ongoing supports for their autonomy, competence, and relatedness, they display increasing amounts of self-determination appropriate to their developmental stage. Behaviors are undertaken with a sense of choice, for they emanate from the self in a harmonious fashion.

When development does not proceed optimally, however, because of biological vulnerabilities or because the social context does not provide autonomy support, competence, and involvement, the organismic integration process will be impaired, resulting in psychopathology characterized by disturbances of autonomy. This may involve blocking awareness of urges and developing rigid regulatory processes, or alternatively, displaying inadequate regulatory capacities and being governed by one's urges. Stated differently, when organismic integration is impaired, people become either overcontrolled or undercontrolled, neither of which is adaptive, for both lack the experience of autonomy. In the case of overcontrol, the development of self is undermined as people regulate action through introjected values and controls, whereas in the case of undercontrol, internalization is forestalled, preventing the development of a well-anchored value system to organize and guide behavior.

In cases of either overcontrol or undercontrol, the perceived locus of causality for behavior lies outside the self, and as such there are compromised or distorted volitional processes (Shapiro, 1981). Such circumstances are especially likely to predominate when caregivers have not provided the interpersonal involvement and consistent responsiveness necessary for forming attachments that support the development of self-regulation in all its forms, including intrinsic motivation, internalization, and emotional integration.

Given the generality of this description, it is perhaps more clear why we stated at the outset of this chapter that, although varied in its form and etiology, psychopathology typically entails *impairments of autonomy* (Angyal, 1965), representing failures in organismic integration and the development of self. From the perspective of SDT, explicating the autonomy disturbances that result from failed integration involves a consideration of the dialectical interplay between the psychological needs for autonomy, competence, and relatedness that subserve organismic integration and the social contexts that either nurture or thwart the individual with respect to these psychological needs.

The workings of this dialectical relationship were discussed in the review of research on intrinsic motivation, internalization, attachment, and emotional integration—or, more to the point, on the impairments of those processes. Some of that research was conducted with nonclinical samples and some with clinical populations. However, in what follows we focus on specific disorders, both in terms of a theoretical account of autonomy impairment and a review of relevant research. We argue that the processes that hinder intrinsic motivation, internalization, attachment, and emotional integration are frequently the same processes underlying the disturbed autonomy evident in various forms of psychopathology.

Focusing on these processes, we discuss three general types of autonomy disturbances. First, we consider those in which rigidly introjected controls dominate one's psychic reality. Although there are a variety of internalizing disorders in which introjects play a critical role, we discuss a select few for illustrative purposes. To do that, we begin with a review of Shapiro's (1965, 1981) conception of rigid character as a dimension in psychopathology and then turn to specific diagnostic categories, including Obsessive-Compulsive Disorders, in which internalized but unintegrated pressures and mandates exert periodic regulatory influence over behavior and thought; paranoid personality, in which introjected punitive controls are projected onto the environment; and both self-critical depression and eating disorders (i.e., anorexia and bulimia), in which unreasonable

and unattainable introjected standards dominate one's experience and lead invariably to harsh self-evaluations and self-disparagement.

To illustrate autonomy disturbances based in failures to internalize significant values and regulatory processes, we focus on selected externalizing disorders. In these cases, the structures and processes to manage one's urges or to regulate intentional actions are often transient, and there is an emphasis in personality on need substitutes and goals that function to support an impoverished core sense of self. To illustrate these types of autonomy disturbance, we first discuss problems of impulsivity and then focus on motivational dynamics in Conduct and Antisocial Personality Disorders and in Dissociative Identity Disorders.

Finally, we address autonomy disturbance in the context of personality disorders by addressing borderline syndromes. Here our focus is on the integrative difficulties posed by controlling and inconsistent environments that produce the self-pathology associated with these personality styles.

In discussing each of these types of autonomy disturbance our approach is twofold. First, we illustrate how autonomy issues are integral to the disorders, in the sense that phenomenological and regulatory issues related to autonomy and perceived locus of causality are characteristically skewed. Second, we discuss factors relating to the social context of development that contribute to the etiology of these disorders. Although it is the case that any factor that disrupts the organizational tendency, whether biological, interpersonal, or cultural in nature, can potentiate disturbances of autonomy, in many cases the sources of disrupted autonomy can be directly traced to deficiencies in the social environment—that is, to its failure to provide appropriate autonomy support, structure, or involvement.

Internalizing Disorders and Autonomy

The process of introjection is central to a substantial amount of psychopathology. When values, regulations, and standards are taken in but not integrated, they exist as forces dissonant with one's true self that pressure one to act. Thus, many instances of maladjustment involve introjection, particularly those often described as internalizing disorders.

Rigid Character

One class of psychopathology for which introjection is a defining feature is what Shapiro (1981) labeled "rigid character disorders." Rigid character involves an ongoing struggle with authority that begins as a conflict between the strict demands of a socializing agent and the person's

own organismic urges and desires. Over time, the person moves the conflict inside by introjecting the demands in the form of rigid, internally controlling structures that hold the urges in check.

Rigid introjects, though products of socialization, regulate action in part through blocking awareness of the person's organismic needs and urges (Rogers, 1951). This victory of the introjects is a peculiarly distorted one, for the person will align with the internalized authority by relinquishing aspects of his or her own organismic nature. Indeed, the process of introjecting rigid structures often results in the type of self-deception in which the person thinks he or she wants what the authority originally prescribed. This is an instance of what Winnicott (1960/1965) referred to as false self, in which cognitive functions gradually lose their grounding in organismic processes. Resolution of the authority conflict by introjecting the authority is therefore accomplished at the expense of a person's need for autonomy.

Intentionality in rigid character disorders is characterized by its heteronomy and inflexibility. Heteronomy is manifest in the pressured experience, backed by threat of anxiety, that drives much of the person's action, and inflexibility is evident in the absence of openness to novel ways of doing things or consideration of alternative values. Rigid character, with its internally controlling regulation, has a clear parallel with what we have observed in research on ego involvement where self-esteem is hinged on particular outcomes so the person is pressured to perform (Ryan, 1982).

The internally controlling regulation of rigid character can, in some instances, be highly stable and self-sustaining, in part because it can yield ongoing external approval and derivative internal gratifications. Among these gratifications are what Deci (1980) referred to as need substitutes. In the case of rigid character, for example, the person will have developed a strong motive (or pseudo-need) to be in control as a substitute for the innate, though unsatisfied, need for autonomy. The substitute need for control is reflected in the exercise of will power (Shapiro, 1965), which Deci described as internally controlling regulations countering one's drives and emotions. Similarly, Lewin (1951) suggested that will power involves concealing the motives that run counter to the controls, and May (1969) asserted that will power involves rationalization and self-deceit. These various views converge to emphasize that rigid internal controls function to block conflicting aspects of the person from awareness, thus allowing the person to disown them. This self-deception is both a result of and a contributor to fore-stalled organismic integration, and thus represents impaired

autonomy even though it involves clear intentionality and mental determination. In this vein, Shapiro (1981) described such displays of will power as “pseudo-autonomy.” As an example of rigid character, we turn first to a discussion of obsessive-compulsive disturbances.

The Obsessive-Compulsive Disorders

Two separable diagnoses carry the rubric of obsession and compulsion: Obsessive-Compulsive Disorder (OCD) and obsessive-compulsive personality (OCP). These two distinct entities share some common features in the dynamics of behavior regulation, but they also differ in meaningful ways. OCD, an Axis I disorder, is characterized by the experience of intrusive thoughts and demands that typically can be alleviated only by engaging in some ritualistic, rigid behavior. The thoughts are often ego-dystonic, in that they are unwelcome and anxiety-provoking, and thus are experienced as having an origin outside the self. Indeed, these thoughts often are inconsistent with the person’s conscious values and ideals. An example is a woman who was diagnosed with OCD and who reported continuing intrusive thoughts concerning hurting her baby whenever she was near certain objects. These intrusive thoughts raised considerable anxiety precisely because they ran against her seemingly strongly held desire to keep her child safe. To alleviate this anxiety she was compelled to check continuously for dangerous objects in her vicinity. Indeed, OCD is classified as an anxiety disorder precisely because obsessions and rituals often have the function of regulating anxiety, albeit usually only temporarily.

An important feature of the dissonant thoughts often found in OCD is that they are persistent, unwanted, and difficult to control. From the perspective of the individual, the unwanted thoughts have an impersonal locus of causality, in that they “befall” him or her. The person then feels coerced into ritualistic behaviors; he or she must do them or face dreadful anxiety. The ritualistic actions that alleviate obsessional thoughts therefore have an external perceived locus of causality. As an aspect of this external causality, compulsive behavior patterns typically are performed under strict constraints; there is an inner demand to engage in actions in rigidly prescribed ways. These orders are experienced as heteronomous forces, albeit ones within the person. The cost of failure is guilt, anxiety, and self-disparagement, and in more extreme cases a sense of panic and fragmentation of the self. The regulatory process of compulsive acts is thus accompanied by a sense of inner pressure that we would describe as internally controlling. For instance, as Swedo and Rapoport (1990) reported, children with OCD often hide their symptoms in public and re-

port feeling that it takes tremendous energy to stave off compulsive enactments. They then feel compelled to release the pressure of resistance at home, leading parents to attribute willfulness and control to a child who feels little of either with respect to these symptoms.

Unlike OCD, there appears to be little evidence for a biological basis to OCP, though temperament has been implicated as an etiologic vulnerability (Sperry, 2003). Supporting the differential role of biology, Jenike (1991) reported responsiveness among OCD patients to pharmacological interventions, but not those with OCP. Also in contrast to OCD, OCP is more a lifestyle than a symptom, and in many ways OCP can be viewed as a continuum, from a somewhat rigidly focused set of attitudes to a disorder that interferes with ongoing functioning. Accordingly, many features of this controlled lifestyle are ego-syntonic rather than disturbing. For example, patients with OCP might exhibit a stereotyped and rigid manner of organizing their possessions and become distraught whenever things appear to have been moved or misplaced. Such individuals might come to treatment not because they view the orderliness as problematic, but because their pattern of living is causing interpersonal or vocational difficulties. In addition, as reported by Othmer and Othmer (2002), persons with OCP often display their characteristic drivenness, compulsiveness, and inflexibility when events involving authority, intimacy, or lack of structure trigger them. Nonetheless, the surface structure of these behaviors bear similarities with the ritualistic behaviors so often manifest in OCD.

It is particularly clear with OCP that the pathology of obsessive-compulsive actions is not defined by the behavior itself, for the behavior can be productive and beneficial. Rather, it is the rigid regulatory processes underlying compulsive behavior that are pathological. Still, the more severe the disorder, the more one’s behaviors become separated from adaptive consequences, and the resulting ritualistic behaviors that serve to bind anxiety themselves become dysfunctional.

Persons with OCP, while not typically afflicted with intrusive or bizarre thoughts, are often inordinately concerned with carrying out the actual or presumed demands of authority. For example, a person with this personality style can be quite industrious and fastidious in complying with the introjected demands, and this may yield high productivity. This industriousness is quite different from the vitality of an autonomous individual, however. A. Miller (1981) described vitality as the freedom to be spontaneous and to experience one’s inner feelings, and Ryan and Frederick (1997) argued that vitality concerns the free energy a person has at his or her disposal. The deter-

mination of the internally controlled individual with OCP involves neither freedom nor spontaneity and is often experienced as energy draining, in much the manner described by Baumeister, Muraven, and Tice's (2000) ego-depletion model. As Sperry (2003, p. 178) noted, the demeanor of someone with OCP is often "grim and cheerless." Moreover, resistance to inner dictates, when possible, may require a gargantuan effort.

There is an interesting point about OCP that highlights an important aspect of disturbed autonomy. Although obsessive-compulsive individuals often act with determination in carrying out introjected dictates, they sometimes display confusion and indecision. The problem especially arises when there is no dictate, no established course to follow. At such times, the person may be rocked with indecisiveness and ambivalence, and decisions that appear trivial can be the source of painful ruminations. This illustrates clearly how dependence on unintegrated controls leaves one without self-direction, without a clear sense of what one wants for oneself. Once a person has blocked access to his or her affective underpinnings and needs, there is no basis for making decisions when a control or rule is not evident. The anxiety of indecision highlights how the determination of the obsessive-compulsive is not autonomous.

Although the obsessive-compulsive disorders represent clear instances of psychopathology with disturbed autonomy, it is not clear, nor theoretically necessary, that they are exclusively *outcomes* of parental control. In fact, evidence has been quite compelling for a biologic contribution to OCD. To date, research on social factors contributing to obsessive-compulsive behavioral patterns has been sparse compared to studies attempting to document the biologic and genetic contributors. There is some evidence, however, that OCD can be related to rigidity and controllingness in one's family of origin. For example, Rasmussen and Tsuang (1986) examined the backgrounds of adult OCD patients and found evidence of strict, orderly, and inflexible religious styles. Hoover and Insel (1984) reported family entrapment as common among adolescents with OCD, but also emphasized the reciprocal nature of adult-child interactions that might produce such patterns.

In contrast, case literatures concerning OCP have more frequently pointed to controlling, often intrusive parenting (Millon, Davis, Millon, Escovar, & Meagher, 2000). For instance, Benjamin (2003) argued that persons with OCP often come from demanding, even coercive parenting environments. Moreover, she suggested that the controlling emphasis is more often on punishment for failures than on acknowledgment of success. However, here, too, systematic

investigation of the social context of development of OCP individuals is not extensive. It does appear, however, that the controlling regulatory styles of those with OCP are more likely to be linked with excessive parental controllingness than is the case for OCD.

Paranoid Personality

According to Shapiro (1981), even more extreme along the dimension of rigid personality formations is Paranoid Personality Disorder, a long recognized diagnosis. However, in his view, whereas the person with OCP struggles with internal dictates and rules, the person with paranoid propensities perceives the struggle to be with external authorities and forces. It is agents outside the person whose control, influence, and intrusions must be resisted. Thus, the experience of heteronomy is projected to the external arena, whereas the struggle in OCP has its locus more in the realm of internal admonitions and rules. Paranoid personality is characterized by scrutiny, suspiciousness, and a strong rigidity of thought. However, because the issues are projected as external, symptoms such as these may be experienced as ego-syntonic. Meissner (1995) argued that underneath the paranoid person's external preoccupations with authority and control is very low self-esteem and a good deal of fearful and depressive ideation. Avoiding such feelings helps explain these patients' strong need to maintain a sense of control. As Gabbard (2000) pointed out, support for the patient's autonomy is especially critical in the treatment of this disorder.

Benjamin (2003) argued that these preoccupations with control stem from family backgrounds often characterized by parents who could be critical, humiliating, and even sadistic. Often, parents themselves were victims of abuse. Because of the harsh treatment they received, persons afflicted with paranoia are on the lookout for danger. These patients do not own up easily to mistakes or errors, as past instances of mistakes and errors may have catalyzed harsh treatment. As well, people with paranoia hide any vulnerability or weakness. Sperry (2003, p. 207) similarly summarized the parental controllingness that confronts patients with Paranoid Personality Disorder with the injunction "You are different. Don't make mistakes."

Here again we see the results of the deprivation of autonomy and exposure to excessive controls in a form of harsh self-controlling regulation of behavior, and in this case, suspiciousness and alienation from others. Here the problems with autonomy preclude relatedness and intimacy, as these require both trust and vulnerability. Accordingly, basic needs for relatedness and autonomy remain frustrated.

Introjection and Self-Disparagement

At the core of many rigid character pathologies are introjected demands that organize intentional behavior. Although this type of autonomy disturbance involves conflict and tension, individuals with rigid character are often able to behave intentionally and satisfy their introjects. There are other types of introjected demands, however, that individuals cannot easily attain, and these invariably result in experienced failure and self-disparagement. These forms of disturbed autonomy, like those of rigid character, begin with individuals' introjecting the demands of authorities and basing their self-worth on living up to those demands. But here, the pathology and experience are quite different, for these individuals' predominant experience is failure and worthlessness. Thus, not only is their autonomy undermined by the introjects and the social conditions that promoted them, but they also feel incompetent and unloved by significant others in their social world. Two such pathologies of introjection are self-critical depression and eating disorders.

Self-Critical Depression. Research on depression and its etiology has increasingly pointed to two distinct pathways to the disorder, each of which can build on biological vulnerabilities. The first is concerned primarily with internalization of excessive demands for achievement and is characterized by harsh self-criticism and guilt (Blatt & Homann, 1992; Nietzel & Harris, 1990); the second is concerned more with the loss of relatedness, love, or attachment. Although both of these vulnerabilities involve self-esteem dynamics, and issues of autonomy and relatedness are intertwined in both, the former, self-critical form of depression is particularly relevant to our discussion of autonomy disturbances and internalization. We thus focus on the self-critical depression syndrome, which has been labeled variously as a disorder of achievement-autonomy (Nietzel & Harris, 1990), introjection (Blatt, 1974), self-worth (Swallow & Kuiper, 1988), and autonomy (Beck, 1983).

By whatever label, this syndrome involves a type of disturbed autonomy in which one experiences dysphoric affect and lethargy resulting from the belief that one is a failure. In this disorder there are rigid standards or ideals that have been introjected, along with the belief that failure to attain them means one is unlovable and unworthy. Thus, the punitive introjects, with their ties to contingent self-worth, leave the person vulnerable to ongoing self-scrutiny, and because with such introjects there is little the person can do that is good enough, he or she will invariably feel worth-

less. In other words, self-disparagement tends to be ubiquitous. Individuals with such introjects are harsher in their self-judgments than in their judgments of others, and these self-judgments often form the precursors to depressive episodes (Beck, 1983).

The phenomenological set underlying self-critical depression is particularly relevant to the understanding of depression as involving disturbed autonomy. With respect to significant self-goals, the individual sees the self as responsible and yet as incapable. Thus, the absence of felt competence to attain internalized goals results in a sense of amotivation (Deci & Ryan, 1985b) or helplessness (Abramson, Seligman, & Teasdale, 1978). At the same time, many of the specific demands on the self to achieve or succeed have the character of "have to" and "must," revealing their phenomenological character as having an external perceived locus of causality (i.e., as being heteronomous with respect to the self). This, of course, is the case with all introjects, as they are both internal to the person yet external to the self.

Although the etiology and course of depression are complex, involving both biological and social/environmental factors, the evidence that parental style can contribute to depressive problems is relatively clear. Factors such as loss of parents (and thus of attachment supports), depression in parents (and thus low involvement and/or autonomy support), and excessive parental controllingness have all been implicated in the development of childhood depression (see S. M. Miller, Birnbaum, & Durbin, 1990). For example, in a study done with adolescents 12 to 18 years old, Noom, Dekovic, and Meeus (1999) found that higher levels of autonomy were associated with lower levels of depressed mood and higher self-esteem.

There has been recent interest in the development of perfectionism, a characteristic highly related to self-critical depression. Individuals with high levels of maladaptive perfectionism (including concern over mistakes and doubts about actions) report having experienced harsh (Frost, Novara, & Rheume, 2002) and authoritarian (Flett, Hewitt, & Singer, 1995; Kawamura, Frost, & Harmatz, 2002) parenting. Further, Enns, Cox, and Clara (2002) found support for a model in which harsh parenting led to maladaptive perfectionism, which in turn was associated with an increased proneness to depression. These studies suggest perfectionism as a pathway through which controlling environments might increase depressive symptoms.

More direct investigations of the parenting environments of self-critical depressives have been increasingly frequent. In one illustrative investigation, McCranie and Bass (1984)

found that women high in self-critical depression had parents who maintained strict control, demanded high achievement, and were inconsistent and contingent in their conveyance of love. Similar results concerning self-critical depression in both males and females were reported by Whiffen and Sassville (1991). Finally, Soenens, Vansteenkiste, Luyten, Duriez, and Goossens (in press) recently showed that parental controllingness predicted not only maladaptive perfectionism, but also the severity of associated depression and self-esteem deficits. Such results are consistent with our speculations more generally concerning the social context leading to introjection and internally controlling states. In this sense, one can view self-critical depression as a chronic and pervasive state of ego involvement in which one continuously fails to live up to the demands and is thus punished.

Anorexia and Bulimia. Bruch (1973), in her classic work on the topic, described eating disorders as pathologies of autonomy. She argued that these eating pathologies typically involve a struggle for control that takes the form of obsession with eating and body image, dynamically staving off a pervasive sense of ineffectiveness. They thus illustrate how bodily states and desires can be manipulated by introjects to preserve the illusion of self-sufficiency and to feel a sense of control with respect to oneself and others. In restrictive anorexia, the introjects around eating and weight are more stable and effective in keeping one's eating behavior in abeyance, whereas in bulimia, there is a more open conflict between rigid controls and akratic eating. Bulimics engage in binge eating—in expressive, uncontrolled consumption—only to be overcome by guilt and self-derogation leading to vomiting or abuse of diuretics.

The psychodynamics highlighted by Bruch (1973) were empirically described in a study by Strauss and Ryan (1987). They found greater self-oppression and self-rejection in both anorexic and bulimic participants than in a matched control group, whereas control-group participants displayed more flexible self-management and self-acceptance than did eating-disordered participants. Furthermore, Strauss and Ryan documented a particularly heightened impersonal causality orientation (Deci & Ryan, 1985a) among restrictive anorexics, which is indicative of an impoverished sense of personal effectiveness.

Internally controlling forms of regulation are readily apparent in the dynamics of eating disorders. Whether anorexic or bulimic, these patients display inordinate concern with how others view them and hypertrophied public self-consciousness. As Plant and Ryan (1985) argued, such

consciousness potentiates an external perceived locus of causality in which one has to conform to the projected views of others. Although a focus on weight is often paramount, eating-disordered patients are typically self-conscious, demanding, and self-critical with regard to many aspects of appearance and behavior, which is experienced as a strait-jacket to the self. And although restrictive anorexics in particular appear to display a high degree of personal control, the regulatory basis of this control is dictatorial and built on a tenuous foundation of ineffectance.

In a recent article focused on an SDT-based account of motivation in anorexia, Vansteenkiste, Soenens, and Vandereycken (in press) described these dynamics in detail. In their view, these patients' focus on thinness is an attempt to gain a sense of security and worth, yet the thinness never seems to supply the self-confidence and emotional benefits they expect. They are never thin enough, yet they continually believe that positive feelings are just a few pounds away. The paradox, however, is that achieving their extrinsic goal is satisfying to some degree, so it further anchors them in this pattern of behavior. These patients often strongly assert that they do feel better when they lose weight, and thus that the pursuit of weight loss cannot be the source of their distress. Indeed, their own experiences seem to confirm that efforts at weight loss are part of the solution. The transitory nature of relief thus creates an addictive quality to the internally controlling drive for thinness.

Whereas the restrictive anorexic can display a high degree of control with respect to eating, bulimic patients often find their control overwhelmed by an impulse to binge eat. Binges typically occur at times of high stress or anxiety, thus showing how their introjected regulatory structures are not sufficiently stable to keep the impulse in check. The binge impulse is often a reaction to the rise of unacceptable feelings or to being controlled or criticized, so it represents an attempt to escape from the painful sense of self that carries the burdensome, introjected standards (Baumeister, 1991). It is interesting to note that, as the psychic threat increases for someone with the bulimic disorder, the person's regulatory capacity becomes weakened, whereas in someone with obsessive-compulsive personality, the regulatory capacity often becomes even more rigid and dominant. The lack of stability of the regulatory introjects in the bulimic thus allows for the akratic action, but the self-evaluative introjects invariably result in self-disparagement and feelings of depression for having lost control. It is interesting to note in this regard that the long-term course for many restrictive anorexics is a shift to bulimic patterns of coping.

Although again there are multiple contributors to the development of bulimia and related eating disorders, the role of familial factors in setting up the dynamics of introjection and internal control are quite salient. Bruch (1973, 1979) has vividly depicted the role of parents in catalyzing anorexia by depriving their daughter of autonomy and the “right to live her own life” (1979, p. 38). Minuchin, Rosman, and Baker (1978) similarly reported high levels of enmeshment and intrusive control in families of eating-disordered patients. Convergent empirical findings are also extant. Strober and Humphrey (1987) reported that both anorexics and bulimics experience their parents as blaming, rejecting, and critical compared to normals. Strauss and Ryan (1988) found evidence for less mutuality of autonomy in the object representations of both bulimic and anorexic participants compared with normals, and lower reported expressiveness in their families.

Each of the disorders we have considered thus far begins with rigid, demanding, critical introjects that are pervasive in one’s psychic makeup. These rigid structures take varied forms and are more or less stable and effective in controlling the person’s actions. In some cases, most notably the obsessive-compulsive personality and anorexia nervosa, the disordered individuals can feel a strong sense of personal control and self-efficacy; the OCP can keep his or her personal affairs quite orderly, for example, and the anorexic can keep his or her body image under control. But these, like the other disorders involving salient introjects, constitute disturbed autonomy and can terrorize the person with contingent self-esteem. They thus emphasize the important difference between personal control and autonomy. That is, being self-controlled can yield desired outcomes, but these actions are not experienced as autonomous or volitional.

We turn now to disorders characterized not by the prevalence of introjects, but rather by their absence. These forms of psychopathology involve the lack of adequate regulatory structures that link one effectively to the socializing context.

Failures of Internalization and the Externalizing Disorders

As we argued earlier, the process of internalization is dependent on certain affordances in the caregiving environment—namely, autonomy support, structure, and involvement—which together facilitate both attachment to caregivers and a readiness to assimilate the values they model. Some caretaking environments, particularly those characterized either by coldness and hostility or by neg-

lect, are conducive of poor quality of attachments and lessened internalization (Weiss & Grolnick, 1991).

Conduct Disorders and Antisocial Personality

The diagnosis of Antisocial Personality Disorder (APD) applies to persons who lie, steal, manifest an impoverished sense of responsibility, are aggressive and manipulative toward others, and show evidence that these patterns are continuations of behavior disorders earlier in life. Children diagnosed with Conduct Disorders, a frequent antecedent of APD, display control problems, lability, a lack of ability to give and receive affection, and delayed or impaired development of conscience. Often, they show an unusual interest in violence and sensational phenomena such as fire or gore (Magid & McKelvey, 1988). Further, self-aggrandizement and egocentrism typically characterize their behavior, and their lying about accomplishments highlights their excessive need to be shored up or esteemed by other people in an immediate way. Like adults with ADP, these children tend to display a lack of conscience. There is no deep concern with what is good or right, no stable sense of “I should.”

Etiologic theories of APD have been varied and include both biologic or genetic factors (such as poor autonomic reactivity) and familial or cultural inputs (see Richters & Cicchetti, 1993). Our contention is that APD is a psychopathology of *failed internalization*, and although internalization may have been made more difficult by biological factors, we maintain that the failure can be robustly linked to deficits during one’s early development in the social contextual factors that are essential for internalization to occur. In short, we suggest that people with APD will have failed to internalize societal norms and moral principles, whether in the form of introjected prescriptions or integrated values.

An internalization conceptualization looks to the family environment for the sources of internalized values of a prosocial nature that seem to be lacking in APD. Although there has been little research or theory directly connecting issues of autonomy support, involvement, or structure to the failure of internalization that characterizes APD, considerable evidence points to their importance. First, there is the general literature on prosocial value development, which locates the sources of such positive values in socialization patterns in the family (Kilby, 1993). Most theorists in this area have taken as their point of departure the idea that value transmission is accomplished through a process of *identification*, in which children emulate or model the values and attitudes of their caretakers. Such theoretical models, of course, implicitly assume that prosocial values

must be “put in” to the psyche rather than nurtured. One might alternatively assume that human nature is already prosocial (Deci & Ryan, 2000) and simply requires conditions of nurturance to express that tendency. In any case, the empirical evidence supports either view insofar as prosocial values are most likely to be acquired (or expressed) when caregiving is characterized by warmth (Maccoby, 1980), low power-assertive discipline (Hoffman, 1960), and autonomy support (Ryan, 1993).

The experience of growing up in a nurturant, caring, responsive familial environment undoubtedly facilitates prosocial values. As Kohn (1990) argued, a person who grows up in such an environment has many needs met and is freed from being self-preoccupied, so perhaps he or she is more able to turn toward homonomous strivings and to focus on others. Furthermore, the person will have been exposed to models of caring and concern about others from figures whom they are likely to emulate. Support for this description comes from many quarters. For example, Ryan and Connell (1989) reported that children who experience a high quality of relatedness to parents were more autonomously motivated in the prosocial domain. Similarly, Waters et al. (1979) demonstrated a connection between security of attachment as measured with the Strange Situation paradigm and prosocial orientations.

Conversely, a variety of clinical and empirical perspectives have suggested that antisocial personality, oriented toward self-serving, manipulative, and hedonically gratifying acts, has its roots, in part, in a cold, inconsistent, and controlling family environment (e.g., Benjamin, 2003; Greenberg, Speltz, & DeKlyen, 1993; McCord & McCord, 1964). A plethora of studies has also shown that the common backdrop to APD and Conduct Disorders of childhood includes such factors as maternal depression, loss, high family conflict, other parental pathology, and impoverished conditions of life that fragment the family (Coie & Jacobs, 1993; Loeber & Stouthamer-Loeber, 1986). All of these factors potentiate a situation ultimately lacking in the basic nutrients on which internalization depends—namely, autonomy support, adequate structure and guidance, and concerted, caring involvement.

One limitation of these models of value acquisition, and their implications with regard to the development of externalizing disorders such as APD, is that they do not focus on how or why children might develop values of a nonprosocial or nonmoral nature, except as a converse or absence of moral internalization. For example, there are probably very few parents who strive to teach their children to be manipulative, materialistic, or Machiavellian, but there are many children who develop such an orientation. Absence of iden-

tification does not explain why one proactively seeks to act in these ways. Thus, a fuller model of APD requires both explaining why internalization fails and why hedonic, aggressive, self-gratifying values predominate instead.

Ryan, Sheldon, Kasser, and Deci (1996) and T. Kasser (2002) have argued that, to the extent that individuals lack the necessary nutrients of autonomy support and caring involvement (and therefore are deficient in the development of self), they often turn to extrinsic, narcissistically oriented values to gain and sustain some minimal sense of power, importance, and worth. Thus, people place more value on issues of material wealth and other exteriorized qualities to the extent that they have not consolidated a secure sense of an inner self. Put differently, to the extent that one is not anchored in a true self, behavior becomes increasingly organized by narcissistically oriented, false-self values. In line with this theorizing, T. Kasser and Ryan (1993, 1996) found in late adolescent samples that excessive emphasis on materialistic values was associated with greater maladjustment, including narcissism and Conduct Disorders.

T. Kasser et al. (1995) examined the developmental antecedents of this greater emphasis on materialism relative to prosocial values and found that adolescents who were more materialistic came from homes where both they and their mother reported that there was less autonomy support, warmth, and security. The researchers also found that more impoverished, high-crime neighborhoods, in confluence with these more controlling and hostile parenting environments, were likely to promote children's placing strong importance on these extrinsic values, a finding consistent with Coie and Jacob's (1993) analysis of Conduct Disorders. Finally, T. Kasser et al.'s analysis of clinical interviews with participants in an at-risk population (defined in terms of maternal psychopathology and low socioeconomic status) revealed that those with greater centrality of materialistic values were more likely to be clinically diagnosed as conduct disordered. In a conceptual replication with a college population, participants who perceived their parents to be controlling (versus autonomy-supportive) and cold (versus warm) were found to evidence a relatively higher centrality of materialism in their value orientation. Finally, a study by G. C. Williams, Cox, Hedberg, and Deci (2000) found that lack of parental autonomy support not only led high school students to hold strong extrinsic values for wealth, fame, and image, but also led to the high-risk behaviors of alcohol and tobacco use, early sexual intercourse, and excessive television watching.

One important aspect of this work is its clarification that environments that fail to support true-self development

promote an emphasis on alienated or substitute needs rather than authentic ones and on the visible trappings of worth. These, in turn, motivate the so-called antisocial personality. The research also highlights the continuity of motivational dynamics between nonclinical and clinical populations.

From the perspective of SDT, the development of Conduct Disorders and an asocial, self-focused goal orientation stem directly from inadequate attachment and failed internalization resulting from an externally controlling, inconsistent, and affection-impooverished social context. To the extent that social values (and the economic conditions that structure them) disable, distract, or fragment the caretaking environment, children will be more oriented to narcissistic goals to gain a temporary sense of worth and importance. Not only is this model applicable to conduct-disordered children, but increasingly to American culture more generally (T. Kasser, 2002). Put succinctly, the more we create conditions that disrupt the quality and stability of familial relationships, the more narcissistically oriented (Lasch, 1978) and antisocial our culture as a whole may become.

Dissociative Identity and the Fragmentation of Self

We have argued that essential to the formation of integrated experience and behavioral regulation is support for autonomy and relatedness. Dissociative Identity Disorders (DID) represent, in most cases, a person whose life experiences were characterized by deprivation of both. People who should have been loving were hurtful, and aspects of the person's life and body over which he or she should have had control were intruded on or violated. Indeed, M. Steinberg and Schnall (2001) reported extremely high rates of early physical and sexual abuse among patients with DID.

DID is highly pertinent to autonomy disturbances because autonomy is closely related to integration, and the violation of self, especially by caregivers, can shatter the integrity that is so essential to autonomy. The splitting of personality has the function of defensively shielding the core self from pain, but the shifts in identity that characterize DID are typically not experienced as within personal control. Indeed, they have an impersonal perceived locus of causality. Depersonalization, another symptom associated with DID, also exemplifies this sense of impersonal causality, as if one's body were acting independently of one's will. As autonomy, or self-rule, depends on a sense of self and an internal perceived locus of causality for behavior, it is clear that autonomy is seriously disturbed in DID.

The perceived lack of personal causation is often part of the despondency these patients report. For example, one patient who came to treatment for depression began to

manifest symptoms of DID. She subsequently revealed repeated sexual abuse by her father, which she had "forgotten." As it unfolded, it was clear that she had been threatened with her life if she ever told anyone, a command she had internalized. Only with a high degree of patient, autonomy-supportive empathy was the history told.

Borderline Disorders: Lack of a Stable Self

Personality disorders have become a predominant concern in clinical settings because of their increasing incidence and thus the personal resources demanded in their treatment. Borderline disorders highlight many issues in character pathology generally, and they represent a prototypic example of structural damage to the self that has been associated with failures in autonomy support and involvement of early caregivers.

The core of borderline disorders is the lack of a cohesive and stable sense of self. Among the central features that are associated with this lack of a consistent and organized self are emotional, interpersonal, and self-esteem lability. Borderline individuals show the externalizing attributes of impulsivity, along with some of the features of internalizing disorders such as susceptibility to depression, anxiety, and fragmentation in the face of self-esteem-related losses. A cardinal dynamic of borderline lability concerns anger, both self- and other-directed, which can result in destructive actions and magnify relationship instability and internal feelings of being overwhelmed and disintegrated. More generally, patients with borderline disorders have difficulty differentiating internal needs from external reality, and they are tremendously dependent on concrete supplies from others to maintain a sense of self. They lack the internal controls to modulate anxiety, which can escalate to panic proportions, particularly when no one is available to contain and comfort them.

Another central feature of borderline disorder is a lack of stable identity and commitment, either to a line of action such as a career choice or to a relationship (Meissner, 1988). Patients with this disorder may, however, latch on to something or someone in an effort to derive a temporary feeling of cohesion, but these choices are often inappropriate or destructive. Commitments are difficult because the borderline individual lacks a stable and cohesive self that can form the basis for sharing in committed relationships or endeavors. Closely related to this is the borderline individual's lack of reflective awareness (Bleiberg, 2004; Fonagy & Target, 1997; Ryan, in press).

Phenomenologically, patients with borderline disorders frequently report being both controlled and helpless with respect to their behavior. They often feel like a victim of

circumstances without a sense of personal initiative or responsibility for the direction of their own fate. One late adolescent patient, for example, reported that prior to self-mutilation he entered into a “lost” state, where the overwhelming impulse to cut “came upon” him (conveying an impersonal perceived locus of causality), while at the same time he felt he could only obtain relief and release from dysphoric self-hate by engaging in such acts (suggesting external causality). In no sense did he feel autonomous and volitional in these acts, but rather driven, desperate, and helpless. Interestingly, these self-destructive acts typically followed events in which he experienced a sense of rejection or abandonment from a sometimes clinging and sometimes harshly critical parent.

Connected with the lack of feeling of autonomy and identity, patients with borderline disorder may feel empty and isolated (Westen, 1991). Clearly, there is a diminution of the true self whereby the individual loses connection to his or her interests and feelings. Patients with this disorder often report feelings of boredom and may engage in impulsive acts, such as substance abuse, careless spending, and binge eating, to counteract such feelings.

Although there is some evidence of genetic contributions to borderline disorder, in that many borderlines appear to have exhibited a “difficult child” temperamental profile, much of the evidence focuses on the early environment of the child. The formation of a stable and cohesive sense of self depends on the integration of positive identifications and thus it is not surprising that theories and research point to the importance of early family relations. Two sets of characteristics have emerged from these literatures: severely impoverished caregiving during the early years, and the parents’ (particularly the mother’s) difficulty allowing the child to move toward self-sufficiency and autonomy (Sperry, 2003). In both cases, the parents are thought to fail to bolster the child’s autonomous self that sets the stage for self functions such as identity and affect modulation. Having been exposed to caregivers who did not provide autonomy support, who were unable to take the children’s perspective, the children failed to develop the sense of reflective awareness that allowed them to be in touch with their own internal states or the internal states of others.

Early caregivers of individuals with borderline disorder have been described as unavailable, inconsistent, and neglectful (Masterson, 1985), with reports of sexual, emotional, and physical abuse (Herman, Perry, & van der Kolk, 1989; Westen, Lodolph, Misle, Ruffins, & Block, 1990; Zanarini, 1997). In one study, 80% of borderline patients were reported to be physically or sexually abused or to have witnessed serious domestic violence (Herman et al., 1989).

Explicating more specifically the affect and behavior regulation difficulties of these patients, Linehan (1993) suggested that patients with borderline disorder come from families that invalidate the affective experience of their children. There is no tolerance for fears or anxieties in the children, and they do not experience soothing or comforting from the parent. Without such care, these children do not internalize the capacity to soothe themselves, resulting in difficulty regulating emotions and tolerating feelings of distress and grief that could help to guide their actions.

According to object relations theorists (Kernberg, 1967; Masterson, 1985), the disorder has its roots in the mother-child relationship, particularly during the phase of separation-individuation when the child is striving to experience himself or herself as separate from the mother. Part of the phase involves a pushing away from the mother. In families of borderline individuals, the mother is not able to tolerate movement toward self-sufficiency as it brings up her own fears of abandonment. Consequently, the mother threatens to withdraw nurturance from the child if he or she moves to act as a separate autonomous individual. In SDT’s terms, the child must therefore decide between autonomy and relatedness to the mother and, because of his or her helpless position in relation to the mother, the child gives up autonomy and the trajectory of true self. The connection to mother, however, is not experienced as true relatedness because it is conflicted and fraught with hostility. Given this level of conflict, there is no “good” object that can support the psychological needs underlying a cohesive sense of self.

The problems of the borderline patient thus illustrate how lack of empathy and consistent involvement and autonomy support undermines intrinsic interests and tendencies, as well as self-regulatory functions—all aspects of the autonomous self (Ryan, in press).

SELF-DETERMINATION THEORY AND THE STUDY OF NORMAL DEVELOPMENT AND PSYCHOPATHOLOGY

Among the central aims of SDT is the explication of the social-contextual conditions that promote optimal development of self. Thus, we have focused considerable attention on specifying the conditions that undermine optimal development—namely, ones that are controlling, rejecting, cold, and chaotic, or in other words, ones that thwart satisfaction of the basic psychological needs for competence, autonomy, and relatedness. In studying normal populations, we have observed the undermining of intrinsic motivation,

the introjection of rigid demands and punitive contingencies, and the failures of internalization resulting in poor modulation of urges and emotions and inadequate self-regulation.

It is our contention that many of the processes that are integral to nonoptimal functioning in normal populations are also central to various psychopathologies. Indeed, we see continuity in the basic psychological needs for autonomy, competence, and relatedness across types of people, developmental epochs, and cultures, suggesting that thwarting of these basic needs, especially when the thwarting is severe, is a critical component of psychopathology as well as more “normal” or transitory maladjustment.

At the same time, in our focus on psychological and social dynamics, we do not discount the role of biological influences but consider them interactive with these interpersonal, familial influences. Thus, someone with biological factors contributing to psychopathology will be more vulnerable to minor deficits in the parenting environment, and furthermore, the biological-based vulnerabilities may lead the child to behave in ways that make it harder for the caretaker to be supportive of the child’s autonomy and relatedness needs.

Grolnick (2002) provided an extensive discussion of such dynamics in her work on parenting environments. She explained how so often parental control is a function of both pressures and ego involvements of the parents, as well as a “pull” to control created by children with difficult temperaments or behavioral tendencies. Unfortunately, such dynamics often create a deepening cycle of difficulties, which, if unhindered, leads to well-anchored disorders in later development. That is, to the extent that caretakers respond by restricting their provision of the critical nutrients for optimal development—namely, autonomy support, structure, and involvement—a negative synergism occurs.

In the studies we have done with abnormal populations, we have found support for our view that disturbed autonomy exists in various pathologies. Further, the work of numerous investigators has confirmed that the caregiving environments of individuals with various disorders were lacking in critical nutrients. We thus see the study of normal and abnormal populations as wholly complementary for explicating the psychological factors involved in psychopathology and for detailing the social-contextual factors that contribute to diminished development and the onset of psychopathology.

The developmental antecedents of disturbed autonomy are multiple, with genetic, biological, interpersonal, and sociocultural factors all being relevant (Cicchetti & Dawson, 2002). Genetic and other biological factors enter

transactionally into interpersonal relationships, facilitating or forestalling the quality of these social contextual inputs, and cultural factors both shape and are emergent from patterns of social and familial functioning. Our focus has been on the social and familial factors, although our aim was not to provide a complete account of the development of autonomy disturbances. Rather, we have attempted to describe the phenomenological significance of autonomy in normal and pathological development and to show empirically and theoretically how interpersonal factors contribute to the etiology of pathologically disturbed autonomy.

Within this approach, we have viewed the development of autonomy as proceeding most effectively in familial and social contexts that provide autonomy support, optimal structure, and interpersonal involvement. In the absence of these necessary social nutrients—in contexts that thwart satisfaction of the needs for autonomy, competence, and relatedness—disturbed self-development is expected, resulting in the emergence of psychopathology. Psychopathology is thus the result of disorganizing influences, of contexts that thwart or forestall personality integration.

We have reviewed a large number of studies indicating that the development of autonomy—the maintenance of intrinsic motivation, the internalization of values and regulatory processes, and the integration of emotions—is facilitated by the contextual nutrients of caregiver attention and interest and of encouragement for exploration and self-initiation. Contexts where interpersonal involvement and autonomy support are absent have been found reliably to diminish autonomous regulation and impair the development of self. The two contextual elements that have consistently been found in our studies to impair autonomy and development—namely, controllingness and lack of interpersonal involvement—have also been emphasized in the clinical literature on the antecedents of disorders that involve either heteronomous introjects or failures of internalization. Thus, there appear to be clear parallels between the results of the empirical explorations of autonomy dynamics in normative development and the conclusions from clinical studies of psychopathology.

CONCLUSIONS AND FUTURE DIRECTIONS

The exciting thing about the convergence between our research results on both normal populations and those experiencing psychopathology is that it sets the stage for further empirical investigations in which autonomy concepts figure heavily. For example, the constructs concerning intrinsic motivation, internalization, and autonomy-supportive

relationships all bear on clinical phenomena, and they help us see the continuity of human needs in diverse populations. For example, whereas theories of internalization have been widely discussed in developmental and clinical literatures by such seminal writers as Freud, Mahler, Erikson, Kelman, Perry, Piaget, and Kohlberg, to name a few, there has been a paucity of empirically based studies of the process and little specific theory about factors that facilitate versus undermine internalization. SDT strives to ameliorate this by providing testable hypotheses, amenable to both experimental and field methods, concerning both how to measure internalization and what predicts it.

At the same time, the specificity of dynamics that lead children down different developmental and adjustment pathways is still largely underexplored. Needed research could begin by comparing diagnostic groups to matched control groups, much as Strauss and Ryan (1988) and Grolnick and Ryan (1990) have done with eating-disordered patients and learning disabled students, respectively. Such strategies help to establish that autonomy disturbances do exist within various clinical problems and to specify the nature of the disturbed autonomy. For example, in disorders involving rigid introjects, it would be important to clarify the strength and centrality of introjects, whether the disordered individuals generally live up to or fall short of the introjected demands, and the nature of the intrapsychic punishment that follows inadequate performance. Additionally, in disorders involving inadequate internalization, research should clarify the nature of the impulses that prevail, the conditions within which regulation is more versus less effective, and so on.

More detailed work on the antecedents of specific autonomy disturbances within the various disorders will also be important. It is clear, for example, that the lack of autonomy support and genuine relatedness by caregivers is antecedent to the development of a wide range of pathologies (see, e.g., Ryan, in press). Yet, why an individual develops anorexia nervosa rather than pervasive self-punitive depression in familial contexts that are demanding and critical is an example of the kinds of questions that are important to tackle empirically. That autonomy disturbances are involved in a wide range of disorders and that familial and other interpersonal contexts play a role in their development seems certain, and of course bespeaks SDT's claim of the generalized nature of autonomy-related needs for psychological development. Nonetheless, the more specific processes through which autonomy is derailed and how these processes are linked to specific disorders or symptoms remain to be further clarified. Failures of autonomy support appear to supply a generalized stressor to integrated development, but how this

differentially impacts and interacts with varied diatheses is an area for rich empirical inquiry. The challenge this provides is at once formidable and intrinsically interesting.

The theoretical framework of SDT specifically distinguishes autonomy from independence, and this distinction is one we see as particularly critical to the field of developmental psychopathology, as well as to theories of parenting, attachment, and development more generally. Noting that both independence and dependence can be either heteronomous or autonomous can help future researchers disentangle what heretofore has been a very mixed and confused literature on dependency across the life span (La Guardia & Ryan, 2002). In our view, dependence should be considered not only as a potential problem, but also as a positive capacity. The willingness to rely on and receive support from others is a basic human propensity that is fostered when autonomy is supported (Ryan et al., 2005). Future research can thus build on this distinction, examining more clearly the pros and cons of dependencies in different developmental epochs and interpersonal contexts. It can also inform the growing literature on psychopathology as it relates to gender and culture, where issues of autonomy and independence have too often been melded and confused (see Chirkov et al., 2003).

More generally, we have pointed in this chapter to the connections between the development and integration of personality and the phenomenological experience of autonomy in the regulation of behavior. In our view, the issue of autonomy is a critical one for organizational perspectives on developmental psychopathology because it supplies a deeper meaning to the concepts of organization and integration than mere synchrony or coordination between systems. That is, the experience of autonomy in action is a defining feature of organization, whereas disturbances of autonomy correspond to fragmentation and disorganization in psychological development. We have further pointed to environmental conditions that either thwart or nurture needs for self-determination, competence, and relatedness as determinative factors in development either away from or toward greater organization and integrity, respectively. The differentiated study of how these psychological needs, in interaction with the biological and social conditions of development, result in relative integration and, thus, experiences of integrity and autonomy in action supplies a broad and important agenda for future clinical research.

Implications for Prevention and Treatment

An interesting question for future research concerns the relationship between *etiological factors* such as lack of auton-

omy and impoverished relatedness and *ameliorative factors* proposed by various treatment approaches. It seems clear that the absence of need-supportive inputs from caregivers can create a cascade of negative developmental processes, both behavioral and biological, that can eventuate in disordered functioning. Prevention efforts thus must focus on attempting to create need-supportive environments for the developing child through, for example, parent education or school reform. On the other hand, ameliorating or treating existing disorders (i.e., tertiary approaches) may entail addressing need deficits both directly (by providing a need-supportive therapeutic context) and/or indirectly (e.g., by providing people with skills or opportunities to better satisfy needs in their natural environment or better cope with maladaptive patterns due to deficits).

Implications of this work for a preventive viewpoint are clear. Indeed, insofar as SDT represents a social psychology of personality development, it offers very specific ideas concerning optimal parenting and teaching. It details, for example, how adults can set appropriate limits (Koestner et al., 1984); how to use praise and rewards effectively (Deci et al., 1999); what familial conditions foster positive value internalization (Grolnick, Deci, & Ryan, 1997); and what a need-supportive classroom environment that fosters learning and self-esteem development entails (Deci & Ryan, 1985b). Moreover, SDT suggests that different cultural practices and social values can differentially affect psychological development (T. Kasser, Ryan, Couchman, & Sheldon, 2003; Ryan et al., 1996). Thus, a body of practical knowledge is emerging from these decades of work on autonomy that concerns how environments can nurture psychological integrity and wellness, one with considerable cross-cultural generality (Ryan & Deci, 2003). However, these understandings have yet to be systematically applied in empirically supported prevention work.

An exception to the paucity of prevention efforts is the Child Development Project (CDP; Solomon, Watson, Battistich, Schaps, & Delucchi, 1996), a school-based reform initiative that focuses on students' needs for autonomy, belongingness, and competence experiences in the context of schools. The CDP specifically emphasizes cooperative learning, the importance of democratic values, student autonomy and self-direction, and a child-centered approach to classroom management in its efforts to meet the psychological needs of students and thereby foster greater school engagement and personal development. Recent evidence suggests that in schools where the CDP approach has been adequately implemented, students show gains in personal adjustment, positive social and ethnic attitudes, internalization of values, and greater self-motivation (Solomon,

Battistich, Watson, Schaps, & Lewis, 2000). Similarly, First Things First (Connell, 1996), a school reform initiative that draws on SDT concepts, has shown empirically verified success in increasing student motivation, engagement, and performance in impoverished urban school districts. The fact that school-based programs focused on supporting psychological needs can effectively alter the course of development suggests the promise of prevention efforts for ameliorating some of the deficits that stem from earlier caregiving deficiencies.

Indeed, the possibilities for prevention are manifold, and the fact that they can succeed raises an important question concerning the relations between prevention efforts and *resilience*. The concept of resilience suggests that there can be protective strengths, either in the individual or the environment, that can ameliorate or forestall the deleterious impact of otherwise toxic environments. Evidence from SDT-based studies of within-person variability over partners, contexts, and time strongly suggests that there is considerable plasticity within persons, such that when individuals find themselves in contexts where psychological needs are supported, they function more optimally, regardless of vulnerabilities or general tendencies. Even an insecurely attached person is more secure in need-supportive contexts (La Guardia et al., 2000); even a detached person may be more likely to reach out when another is empathic and noncontrolling (Ryan et al., 2005). Thus, the presence of even one significant figure who can provide support for basic psychological needs may foster a greater resilience, even amid a social backdrop characterized by negative events and risk factors. This within-person plasticity, so evident in our recent studies (see Brown & Ryan, in press), thus has many implications for the literature on resilience and the design and focus of interventions. Future research should capitalize on within-person methodologies to look at the protective influences that contextual and person-specific sources of support can provide.

Although primary prevention using SDT principles has not been widely attempted, the past few years have seen an increasing interest in applying SDT's formulations in tertiary treatment settings. In particular, promising advances are being made in SDT-informed treatment for addictions, including alcohol, opiate, and tobacco dependencies (Foote et al., 1999; Ryan, Plant, & O'Malley, 1993; G. C. Williams, Deci, & Ryan, 1998; Zeldman, Ryan, & Fiscella, 2004). These studies particularly point to the critical role of patients' volition in successful treatments and how clinicians' autonomy support can foster and sustain that volition. There have also been several articles connecting SDT with the effectiveness of treatments con-

gruent with that theory. For example, W. R. Miller and Rollnick's (2002) motivational interviewing approach has been directly linked to SDT principles in terms of its effective ingredients (e.g., Markland, Ryan, Tobin, & Rollnick, in press; Vansteenkiste & Sheldon, in press). In addition, treatments such as Linehan's (1993) dialectical behavior therapy for borderline and other personality disorders focus on providing autonomy and relatedness supports, a focus for which SDT supplies theoretical justification (Ryan, in press). Sheldon, Williams, and Joiner (2003) have also detailed clinical applications of SDT in health care and counseling settings. These and other papers are increasingly showing the applied value of a basic human needs approach in the clinic.

Additionally, new research is showing how those who treat children with severe psychopathology can themselves suffer stress, which affects the quality of their care and their degree of controllingness (e.g., M. F. Lynch, Plant, & Ryan, in press). That is, psychiatric workers who are stressed and themselves feel more threatened or unsupported tend to have more controlling styles of intervention. At the same time, the data also show that children in such psychiatric care are more likely to positively engage their treatment when the climate supports their autonomy. Such research suggests that an important element in settings concerned with educating, housing, or intervening is an institutional support for the autonomy of the adults involved, which can provide these adults with the psychological resources that allow them, in turn, to nurture and support the children in their care.

Summary

The postulate that there is a core set of basic psychological needs across development and cultures has yielded many testable hypotheses and generative directions for research, a prospect that is both exciting and daunting. It seems clear that experimental and field studies using SDT can contribute descriptively and prescriptively to the field of developmental psychopathology, while at the same time the study of psychological disorders also sheds light on the specific ways in which need thwarting impacts healthy developmental processes. Moreover, SDT's emphasis on need support has much to say about the design of social contexts and the priorities to be stressed in our families, schools, and treatment facilities. Of course, it is the enhancement of autonomy, relatedness, and competence of individuals that supplies an intrinsically valued rationale for the continuance of this work.

REFERENCES	884

In this chapter, person-oriented research strategies in developmental psychopathology are reviewed. By person-oriented, we mean research strategies where the focus is on the individual and not on the variable. The information about each individual is regarded, as far as possible, as an indivisible unit, both conceptually and in the empirical analyses. The term usually implies that individuals are studied on the basis of their pattern of information in relevant variables at the appropriate level. This approach is in contrast to the standard variable-oriented approach, where the variable is the main conceptual and methodological unit. In the person-oriented approach, most commonly the variable alone has no importance. Only in combination with other variables in an information pattern does it achieve meaning. These fundamental conceptual and theoretical issues are discussed in the next section.

In this context, it is important to make a distinction between the person-oriented approach as a *theoretical* perspective or framework, as characterized earlier, and its

consequences as a set of pattern-based methods of analysis, which are usually applied to carry out a person-oriented approach.

It is customary in this type of review to draw heavily on earlier work by the current authors as well as others, and this chapter is no exception. This will be clear from the references. Specifically, in some sections material is borrowed from an article that appeared in *Development and Psychopathology* (Bergman & Magnusson, 1997).

After providing the theoretical background to the person-oriented approach, it is our aim to review major types of person-oriented methods that we believe can be useful in research on developmental psychopathology. To make this review more concrete, we also present empirical examples that illustrate some of the methods. We do not claim to cover every method or approach that can be of use to carry out person-oriented research; the methods presented are our selection and they may reflect our own biases. The empirical examples are drawn from our own work, and the

methods we have been involved in developing have in some cases been given more extensive attention than other methods. This should not be regarded as indicating that we consider the methods we have worked with as more worthy of focus than other methods. Finally, we discuss issues in implementing a person-oriented research strategy and perspectives for future research.

THE HOLISTIC-INTERACTIONISTIC RESEARCH PARADIGM AND THE PERSON-ORIENTED APPROACH

During the past decades, the concept “person approach” has become increasingly used in developmental research. It is a powerful concept that is important for meaningful scientific communication of theoretical ideas and for correct interpretation of empirical studies to clarify its contents. In this section, as a frame of reference for the further discussion of research strategies and methodological tools in research in developmental psychopathology, we emphasize the distinction between the person approach as a theoretical, paradigmatic concept of the individual as an integrated human being, that is, the holistic-interactionistic perspective, and the appropriate measurement model and its research strategy consequences (see Magnusson, 2003).

The Holistic-Interactionistic Perspective

As a theoretical concept, the person approach means making the individual—as an integrated psychological, biological, and social organism—the organizing principle for scientific inquiry. In developmental research, including research in developmental psychopathology, this proposition entails a holistic perspective. With reference to a holistic-interactionistic view on individual functioning and development, the role of the person approach has been analyzed by Magnusson (1985, 1999a; Magnusson & Allen, 1983), and its methodological and research strategy implications have been discussed by Bergman (2001), Bergman, Magnusson, and El-Khoury (2003), and Magnusson (1998a). Their applications in research on developmental psychopathology have been underlined in Bergman and Magnusson (1997) and Stattin and Magnusson (1996).

From a theoretical perspective, the person approach rests on two fundamental characteristics of developmental processes: (1) They are indivisible, that is, holistic in nature; and (2) a key principle in the functioning and development of the integrated individual is *functional interaction*.

The Holistic View

At a general level, a holistic view has ancient roots. From the beginning of the twentieth century, from H. William Stern (1917) onward, the holistic perspective was emphasized by researchers, particularly in developmental and personality research (see, e.g., Magnusson, 1999b, pp. 223–224). For a long time, however, the holistic view had little, if any, impact on empirical psychological research in general, including developmental research. The reasons for this state of affairs were numerous. Clark Hull (1943) argued that the lack of relevant knowledge of internal psychological and biological processes had the effect that psychological research had to be restricted to “molar behavior.” For decades, this view was reflected in classical interactionism, concerned with person-by-situation (environment) interaction, expressed in the well-known Lewin (1936) formula $B = f(P, E)$. In empirical applications, classical interactionism did not include internal working components in the analyses of individual functioning and development.

An increasing number of voices, however, proposed models that help to overcome the limitations of the empty holistic model (see, e.g., Baltes, Lindenberger, & Staudinger, 1997; Cairns, 1979; Cairns & Valsiner, 1984; Emde, 1994; Magnusson, 1985; Wapner & Demick, 1998). Four sources have contributed to overcome this restriction for empirical research and to form the theoretical basis for a modern holistic-interactionistic approach to research on individual functioning and ontogeny (Magnusson, 1998b, pp. 497–498):

1. Research on mental components of individual functioning (information processing, learning, memory, emotions, and values). Research in these areas has gained much from cross-disciplinary approaches in neuroscience.
2. Cross-disciplinary psychobiological research on the interaction of mental, biological, and behavioral components of integrated processes. Progress in research on this issue has been important for understanding developmental processes in general. For psychopathology in particular, the psychobiological research has played an essential role in the understanding of the developmental background of antisocial behaviors.
3. The formulation of models for dynamic, complex processes, including general systems theory and chaos theory. Particular interest is the emphasis in these models of the holistic character of such processes. Among other things, this implies that dynamic, complex processes cannot be understood and explained by the

combination of results from studies of isolated components of the process, independent of other simultaneously working components. This proposition has decisive implications for the methodologies and research strategies that are appropriate in a person approach. However, the correct application of these models is not easy. It presupposes awareness of the fact that human functioning and ontogeny are guided by insight, intentions, emotions, and values. This makes the application of dynamic models that take this into account a very demanding task.

4. Well-planned longitudinal studies that have contributed basic knowledge about individual development. These have strongly demonstrated that it is the integrated human being that keeps its identity and develops over the life span, not single variables.

These contributions have allowed the formulation of a modern holistic-interactionistic theoretical perspective as a frame of reference for the design, implementation, and interpretation of studies of specific aspects of developmental processes (see, e.g., Magnusson, 1990; Magnusson & Stattin, 1998; Magnusson & Törestad, 1993). An individual functions as a totality at each stage of development. Each component of the structures and processes that are operating at a certain level takes on meaning from the role it plays in the subsystems, in order to maintain the organism's integrity in current functioning and in developmental change, within the limits set by its potentials and restrictions. This implies, among other things, that the individual *as a whole* must be considered as the framework for planning, implementing, and interpreting empirical research on specific aspects of individual functioning in a current and a developmental perspective. The application of such a general perspective is a necessary condition for the synthesis of knowledge about why individuals think, feel, act, and react as integrated human beings, both in a current and a developmental perspective.

A basic concept in discussions of individual development is that of *change* of involved structures, which can concern both progressive and regressive change in a life span perspective. From a holistic perspective, individual developmental change is analyzed and discussed in terms of integrated, dynamic, and complex processes. The holistic nature of these is a characteristic of human processes at all levels, from the cellular level to the individual's interaction with his or her environment. Within subsystems, for example, the immune system, the coronary system, psychobiological subsystems, and cognitive subsystems, the operating components work in an integrated way to satisfy

the whole organism's need for stability and integrity in the process of developmental change. In the integrative process, each level has properties that are not the summary of processes at a lower level; new properties emerge from level to level. Accordingly, the integrated individual has properties beyond what belongs to the parts. The consequence is that empirical analysis must always be performed with data from a certain level of individual functioning. Mixing data from different levels inevitably leads to erroneous results.

Functional Interaction

It was emphasized earlier that the integrated nature of developmental processes means that they cannot be understood and explained as the summary of mental, biological, behavioral, and social elements; together they are simultaneously involved in holistic, synchronized processes at all levels of the whole organism. A fundamental principle in these processes is then the *functional interaction* among involved components. Functional interaction is a central concept in biological models for living organisms (Mayr, 1997). Individual developmental change processes get their characteristic features and properties from the functional interaction among the operating elements involved, not by the effect of each part separately on the totality.

There has been a tendency among psychologists to dismiss the role of interaction in psychobiological processes as too vague. In contrast, in theoretical and empirical biological research, functional interaction is a basic concept, and this principle is equally applicable to psychological research on the functioning and development of the human being. Acceptance and application of this proposition is, in our minds, a requirement for further progress in line with what happens in other life sciences.

Developmental Crystallization

The holistic-interactionistic perspective implies, among other things, that a process of *developmental crystallization* occurs (Magnusson & Mahoney, 2002, p. 234). According to this proposition, the developmental processes of individuals whose system organization differs at a certain point in time (as a result of different constitutional factors, maturation, and experiences) will take partly different directions in the next step. In that process, each step confines future developmental alternatives, and eventually more stable "types" than those at the beginning will emerge. This should show up in a clearer homogenization in categories of individuals and a more clear differentiation among categories of individuals across time. The issue of interindividually different life paths was discussed by Moffitt (1993)

on theoretical grounds and by Magnusson (1996) with reference to results of empirical, longitudinal studies on anti-social behaviors.

The crystallization hypothesis was supported in an empirical study on what was designated “problem gravitation” by Bergman and Magnusson (1997). This study is briefly reviewed in a later section in this chapter. In a similar way, Loeber, Keenan, and Zhang (1997) found different trajectories for a sample of boys with problem behaviors (see also, e.g., Robins, John, Caspi, Moffit, & Stouthamer-Loeber, 1996).

Comment

The holistic-interactionistic perspective has fundamental methodological and research strategy consequences for empirical research on human ontogeny; they are discussed later in this chapter. However, it is interesting to note how little these have been observed and taken into account in developmental research. This state of the art is an illustration to Rom Harré’s (2000, p. 1303) essay in *Science*, in which he made the following observation:

It is a remarkable feature of mainstream academic psychology that, alone among the sciences, it should be almost wholly immune to critical appraisal as an enterprise. Methods that have long shown to be ineffective or worse are still used on a routine basis by hundreds, perhaps thousands of people. Conceptual muddles long exposed to view are evident in almost every issue of standard psychological journals. This is a curious state of affairs. New pathways and more realistic paradigms of research have been proposed, demonstrated, and ignored.

The frequent mismatch in psychology between the scientific problem and the method chosen to analyze it has also been pointed out by Richters (1997).

To accept and apply the holistic, interactionistic perspective in empirical research on human ontogeny follows the development in other life sciences, particularly biology. As early as 1945, the biologist Novikoff, in an article in *Science*, analyzed the main elements of a holistic perspective for research on living organisms. The role of a holistic or, as the biologists prefer to call it, an organismic model for research on living organisms has been eloquently discussed by Mayr (1997) with reference to its history and its present application. In a lecture at the Swedish Academy of Sciences in April 2003, Thomas Rooswall, the director of the International Council of Scientific Unions, summarized what he regarded as the two main common demands for progress in empirical sciences: holistic and cross-disciplinary approaches.

If psychology aims to be a constructive member of the scientific society, then it is high time we adopt the basic

frame of reference for true scientific work in other life sciences and take the methodological and research strategy consequences of this frame of reference seriously.

The Person-Oriented Approach, Its Assumptions, and Conditions for Its Viability

The close alliance of the person-oriented approach to the holistic-interactionistic paradigm should now be obvious. To increase our understanding of the approach, it is informative to take a closer look at the assumptions behind the person-oriented approach and conditions for its viability. Individual development can be conceptualized as a process, characterized at a given time point by its state in multidimensional space, and with state change taking place in continuous time. (By “state,” we mean the specific configuration of values of the process model in the variables characterizing the system under study at a given point in time.) Bergman and Magnusson (1997) made the following five assumptions about the basic properties of this process:

1. The process is partly specific to an individual.
2. The process is complex and contains many interacting factors at different levels. They may have complicated relations to each other.
3. There is coherence and structure (a) in individual growth and (b) in different individuals’ process characteristics. The lawfulness of the processes in functionally organized structures is found in the development and functioning of the systems at different levels. Assumptions (a) and (b) are similar to those made by Magnusson (1988) when he characterized an interactionistic approach in psychological research.
4. Structures are organized and function as *patterns* of operating factors, where each factor derives its meaning from its relations to the others.
5. At a system level, a limited number of more frequently observed patterns (“common types”) will often be found. This assumption is made intraindividually (across development for the same person) and interindividually (across individuals at the same time or over time).

According to Bergman and Magnusson (1997), the assumption of emerging types receives support mainly from two sources:

1. Analogies to system theoretic thinking. Normally only a small number of system constructions and states are in some sense optimal and lead to a stable functioning of

the system. Psychobiological systems have the capability of self-organization. This is a characteristic of open systems and means that new structures and patterns can “spontaneously” emerge, even from chaos (Barton, 1994; Thelen, 1989). Self-organization is a guiding principle in ontogeny, where the operating factors organize themselves to maximize the functioning of each subsystem in relation to the whole system. Such an arrangement has survival value and therefore it persists. Many human biological systems have such characteristics, for instance, the brain and the coronary system. These principles can also be applied to the development of the sensory and cognitive systems (Carlson, Earls, & Todd, 1988; Cicchetti & Tucker, 1994).

2. Support for the assumption of emerging types is also suggested by many examples of biological systems for which distinct types are found (e.g., of species, ecotypes; see Colinvaux, 1980). When studying developmental personality types, Block (1971, p. 110), talked about “‘system designs’ with more enduring properties” and Gangestad and Snyder (1985), when discussing the motivation for a typological approach, talked about distinct types, with each sharing a common source of influence. Summarizing their own position, Bergman and Magnusson (1997, p. 294) stated, “Viewing individuals in terms of complex dynamic systems we would expect certain states to be more frequent than others, corresponding to optimal patterns and it seems natural to explain and investigate such systems using a pattern-oriented approach.”

So what are the conditions when a person-oriented approach is viable? Obviously, it is in situations when it is believed that interactions and nonlinearities operate during development and emerging types can be expected, with each type being characterized in terms of data by a characteristic pattern of values in the relevant variables measuring the system under study. In such situations, a person-oriented approach is natural. Many types of methodological realizations of this approach thrive on interactions and are built for handling them.

Limitations of a Standard Variable-Oriented Perspective

Another way of achieving an increased understanding of the circumstances when a person-oriented approach is useful is to examine the limitations of a standard variable-oriented approach from the perspective provided by the holistic-interactionistic theoretical framework. Without denying that a

variable-oriented approach, focusing on relations between variables, can be useful in studying complex systems in a developmental perspective, it is clear that this approach neglects the crucial importance of the fact that the parts together form a totality. Almost always, the variable-oriented approach is also based on the study of linear relationships, studied across individuals, relationships that in the linear models most often are assumed to be equal for every subject in the sample. It should be clear that such an approach is not well aligned to the assumptions of the holistic-interactionistic paradigm. This state of affairs is illustrated by the fact that in many variable-oriented analyses using, for instance, structural equation modeling (SEM), the correlation matrix or the variance-covariance matrix often becomes the raw data to be analyzed and explained. In this way, all patterns in the data that are not captured by this matrix are disregarded. This is a simplification that disregards higher-order interactions, which can produce misleading results (see, e.g., Bergman, 1988a, for illustrations).

Relations to the Typological Perspective

As discussed by Bergman (2000), few concepts have caused so much debate and even resentment in psychology as *type* and *typology*. When reviewing the concept of type, Cattell (1957) indicated no fewer than 45 different meanings of this concept. It is also used in different ways in other sciences, such as biology and anthropology. For an overview of the typological field from a methodological perspective, the reader should refer to Blashfield (1980).

The meaning of a type is that the subjects that belong to it have in common a number of characteristics. It is this combination or pattern of characteristics that is the essence of the type. The properties of a type are often indicated by a profile of values in the studied variables defining the type. For instance, the cluster centroids (the profiles of the cluster means for the variables) for a set of natural clusters would be one way of presenting the types.

With a typological perspective, we mean an approach in which the focus is on a set of class descriptions or types. All typologies have in common that they contain or refer to a number of classes. For instance, the classes could be the result of an empirical classification analysis where cluster analysis was used to produce the clusters. Or they could be ideal types, theoretically derived, with each type being defined by a distinctive description (Bailey, 1994). If these classes fulfill certain criteria for generalizability and so on, then each class can be called a type and the whole collection of classes, for instance the whole cluster solution, can be called a typology. It

should be noted that it is not the clusters and their members per se in the studied sample that constitute the typology, but rather the generic properties of these clusters. A type is sometimes referred to as a *natural cluster*. A number of thoughtful distinctions with regard to type and typology are given by Meehl (1992). He preferred the use of the terms *taxon* for, roughly speaking, a meaningful type and *taxometrics* as a generic name for (his) procedures for searching for taxa. The Meehl approach is discussed in a later section.

When discussing an empirical classification in relation to a typology it is helpful to distinguish between two perspectives of an empirical classification: (1) the description of the properties of the classes in terms of their characteristics (e.g., the cluster centroids are given) and (2) the allocation of subjects to the different classes or clusters. The first aspect is most directly related to the issue of typology and type. An empirical classification analysis is often better at identifying “true” class descriptions in the presence of sampling error and errors of measurement than the analysis is at allocating subjects to the “right” class.

It should be emphasized that a typology, as the term is used here, does not represent anything unchangeable or innate in difference to the classical typologies. This label is often given a typology by its critics but it does not apply to the modern typological approach and the related person-oriented approach. Of course, some degree of stability and generality is implied in a developmental typology, but changing typologies during development and changing types to which an individual may belong during his or her development are of primary interest here. Thus, in a developmental context, we want to study longitudinal typologies and developmental individual differences in membership in different types of these typologies. According to Bergman (2000), a longitudinal typology might be (1) a typology of developmental types arrived at theoretically, (2) an empirically based typology arrived at by analyzing longitudinal data, or (3) a number of cross-sectional typologies from different ages for which the developmental connections are indicated.

In later sections, methods are presented that fall under the heading of (2) or (3). Further discussions of typological issues as well as empirical examples are given by, for instance, Asendorpf (2000) and Robins, John, and Caspi (1998).

MEASUREMENT

In this section, we compare the measurement models for the variable- and the person-oriented approaches to studying development.

Two Measurement Models

Progress in scientific empirical work presupposes, among other things, the application of appropriate methodological tools. That is, the statistics must match the character of the phenomena being investigated. In later sections of this chapter, methods are presented that are suitable for use within a holistic, interactionistic theoretical framework.

It is probably fair to say that in developmental psychopathology, inappropriate measurement models are frequently used: measurement models that do not take into account the holistic-interactionistic nature of the phenomena under study (see, e.g., Granic & Hollenstein, 2003; Richters, 1997). This can be regarded as one aspect of what Harré (2000) meant by the persistence of bad practices in psychology in spite of clear evidence that the approach should be changed. One reason for this situation is the common neglect of the role of measurement models in the research strategy process (Magnusson, 2003). Real progress in developmental research rests on the application of statistical tools using a measurement model that satisfies the assumptions made about the character of the phenomena being investigated.

Developmental crystallization (discussed earlier) has decisive implications for the choice and application of measurement models in developmental research. Here two main measurement models are briefly presented, each with its specific demands and assumptions. The distinction between the two models represents the basic difference between the variable-oriented approach and the person-oriented approach in psychological research, including developmental research. The basic difference between the two measurement models is in the way the psychological significance of a single datum—representing a response to a stimulus, a response to a test or questionnaire item, a rating, and so on—is derived (Magnusson, 1998a, 2003). The two models are shown in Figure 21.1.

According to measurement model 1 (MM1) in Figure 21.1, a single datum for individual A on a latent dimension k derives its psychological significance from its position on that dimension in relation to positions for other individuals, B, C, D, and so on (see Figure 21.1a). MM1 is the measurement model for the variable-oriented approach to psychological research. Empirical developmental research is dominated by the application of MM1. The focus of interest is on a single variable, or a combination of variables, their interrelations (R-R and S-R relations), and their relation to a specific criterion. The problems are formulated in terms of variables, and the results are

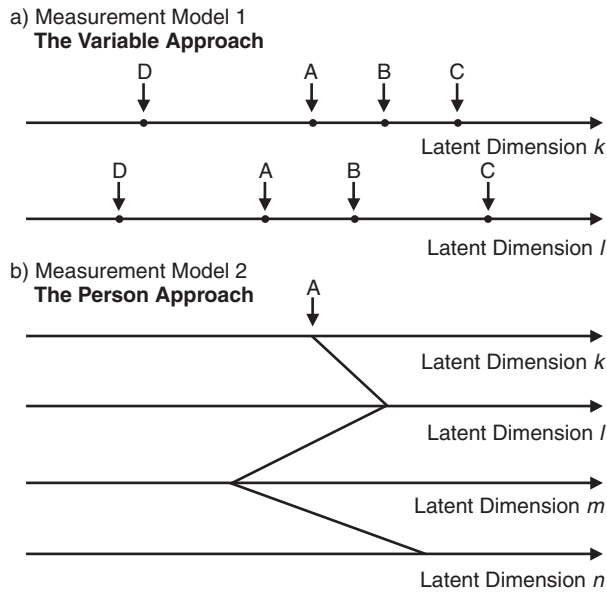

Figure 21.1 Measurement models. *Source:* “The Person Approach: Concepts, Measurement Models, and Research Strategy,” by D. Magnusson, 2003, *New Directions for Child and Adolescent Development*, 101, pp. 3–23.

interpreted and generalizations made in such terms. Statistical models include comparisons between means and other location parameters, correlation and regression analyses, factor analysis, structural equation modeling, and contingency tables. A broad range of statistical tools is available and applied in these analyses. The assumption that should be met in the application of MM1 in research on developmental issues has previously been summarized by Magnusson (1998a).

According to measurement model 2 (MM2) in Figure 21.1, a single datum for individual A on a latent dimension k derives its psychological significance from its position in a configuration of data for the same individual, representing his or her positions on the latent dimensions k , l , m , n , and so on. These latent dimensions are assumed to represent *simultaneously* working components in the system under investigation (see Figure 21.1b). The application of MM2 is the logical consequence of the analysis of many characteristics of individual developmental processes from a holistic-interactionistic perspective. That is, it fits the character of the individual holistic-interactionistic developmental processes. This is the measurement model that is the basis for most empirical realizations of the person-oriented approach. An implication of MM2 is that statistics applying to this measurement model yield information about the individual, and generalizations refer to individuals.

MM2 is applied for two main purposes (Magnusson, 2003, p. 16):

1. To identify groups of individuals who function in a similar way at the organism level under investigation. In terms of data, individuals are categorized on the basis of profile similarity. A number of statistical tools are available for pattern analysis both cross-sectionally and longitudinally. They are discussed in later sections of this chapter.
2. To analyze short-term and long-term developmental processes in terms of patterns evolving in continuous time. Here, models for dynamic, complex processes, derived from the natural sciences, can contribute to the development and application of methods and models with consideration for the specific character of individual processes.

It should be emphasized that both models are relevant and important in developmental research: They are complementary, not contradictory. Each of the models meets specific assumptions about individual functioning and development, and the results of studies applying one or the other of these models will yield answers to different questions (Bergman et al., 2003; Magnusson, 1998a, 2003). Each of them also has implications for the kind of data to be used and the kind of statistical tools that are relevant in a certain study.

Measurement Tailored to a Person-Oriented Approach

Most commonly, the different variables used in a study are not on “naturally” comparable scales. They are often transformed to comparable scales by some kind of standardization of the variables or methods are used, the results of which do not depend on the means and standard deviations of the variables used in the analyses (e.g., Pearson correlations are computed). The results are then invariant to linear transformations of the involved variables. This is frequently the case in variable-oriented settings. Also, in a person-oriented research context, it is often the case that naturally comparable scales are lacking. Normally, then, the variables are standardized before the analysis to ensure that they obtain comparable weights. The reason for this is that the results of many pattern-based analyses are *not* invariant under linear transformations of the involved variables (Bergman et al., 2003).

However, there are situations when we want to undertake a multivariate scaling of all the variables that consti-

tute the pattern so that the values compared between variables and times of measurement contain more information than is given by standardized scores, computed separately for each variable and measurement occasion. To give an example, if we are concerned with studying adjustment problems indicating possible psychopathology and if standardized variables are used, then one has to assume that it is of no importance for the study that different adjustment problems have a varying prevalence in the sample and/or that the same adjustment problem is more common at one age than at another age (because these differences are washed out by the standardization). The limitations of this approach are discussed in Bergman and Magnusson (1997).

Bergman and Magnusson (1991) discussed the issue of multivariate scaling with regard to the measurement and classification of profiles of adjustment problems. They indicated a *quasi-absolute scaling procedure* that is applied to all variables at all measurement occasions. Without claiming that the scaling produced absolute prevalences of the involved adjustment problems (hence “quasi”), the goal was to obtain profiles of adjustment problems that retained information about prevalences and variability of specific problems, as measured by a comparable tally for all variables. Raw information about each adjustment problem (often from more than one data source) was transformed into a 4-step scale characterized by the following approximate meaning of each scale value: 0 = No problem, 1 = Tendency to problem, 2 = Presence of problem, and 3 = Pronounced problem. The quasi-absolute scaling started by applying a subjective procedure in which independent raters were asked to give each type of raw information its weight. Then a mechanical, objective set of rules, based on these weights, was applied for computing the quasi-absolute scores.

When a person-oriented approach is applied, one often must compute some coefficient of profile (dis)similarity, as a basis for the analysis, to compare the (dis)similarity of the value profiles. This is done for each pair of individuals (e.g., to perform a cluster analysis). For a discussion of methods for measuring (dis)similarities between profiles, the reader can refer to Cronbach and Gleser (1953) and Budesu (1980). Two commonly used coefficients of profile (dis)similarity are the average squared Euclidean distance, which takes both profile form and level into account, and the correlation coefficient (with the pair of persons as the two variables and the variables as the cases), which takes only profile form into account. In line with what was said earlier, it is important to point out that neither of these two coefficients is invariant to linear transformations of

the variables in the profile. Such transformations can change the ordering of the size of the (dis)similarity coefficients and, hence, change the results of, for instance, a cluster analysis.

In a person-oriented analysis, the variables included in a pattern are simultaneously analyzed. Often, a proportion of the sample has missing data in one or several variables. However, the standard classification analysis demands complete data in all variables, and subjects with a missing value in one or more variables have to be deleted from the analysis. If a large number of subjects have one or a few missing values, then the deletion of these subjects might not be desirable. Demanding complete data then implies losing many subjects with almost complete data and possibly creating a dropout bias. The solution might be to “guess” missing values for subjects with almost complete data, that is, to perform imputation. To accomplish such a solution, a number of methods are available, which usually are based on linear models (for an overview, see Pierzchala, 1990). However, from a person-oriented perspective, it might be useful to use a twin approach for imputation (so-called hot deck imputation). The imputation procedure is then consistent with the pattern-oriented perspective. In this method, a missing value for a subject is replaced by the corresponding value for the subject with complete data that is most similar to the subject with the missing datum (El-Khoury & Bergman, 1992). It should be pointed out that imputation, of course, produces a temporary file for a certain analysis. The *data* are what they were from the beginning.

MAJOR TYPES OF PERSON-ORIENTED METHODS

In this section, major types of person-oriented methods are introduced.

Methods for Studying the Single Individual

At the heart of understanding individual development lies the intensive study of the single individual. In the field of psychopathology this is, of course, well-known, and this approach is often applied in a qualitative sense, doing, for instance, case studies. However, there are also quantitative methods developed for that purpose that can be useful. John Nesselroade and his coworkers have carried out many developments in this area. For instance, Jones and Nesselroade (1990) advocate a multivariate, replicated, single-subject, repeated measures design that can use P-technique

factor analysis to carry out the analyses. This type of factor analysis has been developed by, for instance, Molenaar (1985). An example of a study of the short-term development of the single individual in the field of psychopathology is presented in Nesselroade and Featherman's (1991) study of intraindividual variability in older adults' depression scores. The subjects were studied on 23 successive occasions, usually 1 week apart. The purpose was to gain information about the stability and magnitude of short-term intraindividual variability. They found evidence for coherent short-term changes, and their results point both to the importance of studying the single individual—and in doing so discriminating between state change and trait level—and to the importance of studying stable interindividual differences in intraindividual variability.

Another set of analytical techniques that can be useful for studying the short-term development of the single individual is time-series analysis, especially if "seasonal" components are believed to be involved in the developmental process. This approach is exemplified by the work of Schmitz (Schmitz & Skinner, 1993). Of course, in this approach, as in the one discussed earlier, one has the problem of how to generalize from a single subject to a population of subjects (see Molenaar, Huizenga, & Nesselroade, 2003, for a discussion of this critical issue). On the other hand, as pointed out by Molenaar and colleagues, this problem does not go away when one carries out a standard interindividual approach of the type discussed later; it just takes another form and can be more severe because the results of such an approach can be claimed to apply to single individuals only under special assumptions. To give just one example: Biological maturation occurs at a different pace for different individuals, and if this is not taken into account in a study, it can contaminate the relationships between the variables that are studied if they are related to biological maturation (Magnusson, 1985).

It is probably no exaggeration to say that most researchers in the field of developmental psychopathology in principle subscribe to a metatheoretical holistic-interactionistic view of the type discussed. Against this background, the quantitative study of the single individual using a dynamic systems approach is potentially attractive, as many evolving phenomena have been shown to be well described by a nonlinear dynamic systems (NOLIDS) approach. In NOLIDS, a mathematical model with differential or difference equations is set up that explains the changes that occur in the observed states of the system under study. Not only can the model handle interactions and nonlinearities, but it also may account for attractor

states such as the resistance of a psychopathological condition to change despite efforts to change it and despite its nonoptimality. A spectacular property of certain NOLIDS models is their capacity to model even very complex behavior such as chaos, with its extreme sensitivity to initial conditions. This raises the hope of being able to explain a seemingly complex phenomenon with a powerful, simple NOLIDS model. For general overviews of NOLIDS, the reader can refer to Gleick (1987) and Jackson (1989), and for discussions of the usefulness of NOLIDS in psychology, the reader can refer to Abraham and Gilgen (1995), Barton (1994), and Smith and Thelen (1993).

However, there are many complications with the NOLIDS approach that are not yet fully solved with regard to the delineation of the system to study and in the estimation of the parameters. Bergman (2001) concluded that useful NOLIDS models in psychology are rare and that often the application of the approach stops at the metaphoric-conceptual level. Exceptions can be found in some more molecular areas that lend themselves to precise inquiry and controlled experiments. A good example is given by Kelso (1995) and his colleagues' work on the dynamics of motor coordination. Extending the study of NOLIDS models beyond the study of the single individual and to take an example of an application of NOLIDS that is closer to developmental psychopathology, Boker and Graham (1998) carried out an interesting NOLIDS study of adolescent substance use. Boker and Nesselroade (2002) also presented a method for fitting differential equations to panel data that appears to be able to recover the parameters of the model based on only three waves of data for a sample of 100 subjects. This is important because standard methods demand many more measurement occasions for that purpose.

Classification-Based Methods

As discussed by Bergman and Magnusson (1997), a typological approach has roots far back in time in psychopathology and abnormal psychology. Such typologies are but a few examples of a basic tendency in human beings to create order in the phenomena around them (for a historic overview, see Misiak & Sexton, 1966; for a review of cluster analysis in psychiatry, see Skinner & Blashfield, 1982). Classification has always had a stronger standing in psychiatry than in psychology, probably because diagnostic classification is basic in medicine. During the previous century, the classification of individuals as a research method became less prominent in psychology. The expansion of sophisticated methods for variable-oriented analysis and hypothesis testing has contributed to this change.

However, as previously pointed out, the person-oriented approach has led to an interest in methods for data treatment focusing on individual value patterns or structures rather than focusing on variables. Classification analysis can be used for this purpose, but a number of methodological alternatives exist for studying interindividual differences in pattern development.

A crude distinction can be made between model-based and mainly descriptive methods (i.e., methods that describe the data without the use of a coherent model). Log-linear analysis (Bishop, Fienberg, & Holland, 1975) is an example of a model-based method without latent variables. In this method, a statistical model is created for explaining the cell frequencies (or rather, the logarithms of the cell frequencies) in a higher-order contingency table. So, in the sense that the multivariate outcome pattern is the dependent variable rather than variables considered singly, it is a person-oriented method. This type of approach has also been tailored to the study of change (Clogg, Eliason, & Grego, 1990). One class of model-based methods with latent variables is based on latent class analysis, for instance, latent transition analysis. This method is presented after the descriptive methods have been overviewed. We start by discussing cluster analysis-based methods for studying the development of psychopathology. Before this, however, it is helpful to give a short overview of some principles of cluster analysis.

Cluster Analysis

The basic idea in cluster analysis is that subjects are sorted into mutually exclusive clusters (classes) according to their similarity. Hence, subjects that are alike are assigned to the same cluster. There are also methods that allow overlap between clusters. Although such methods have attractive properties, they are not further discussed here as they seem often to lead to interpretational problems (Wiener-Ehrlich, 1981).

A wide variety of methods for cluster analysis exist. Most of them use the (dis)similarity matrix between all pairs of subjects' value profiles as the basic data for analysis. The elements in this matrix are usually calculated by applying some formula for computing a (dis)similarity coefficient, based on quantitative information in a number of variables, constituting the value profile. Other methods for obtaining (dis)similarities are, of course, possible (e.g., raters could be used to directly obtain the [dis]similarities).

Two major types of cluster analysis are hierarchical methods (agglomerative or divisive) and partitioning methods. In each type, many methods and algorithms exist, and

there is no method that is generally considered superior to the other ones. The sensitivity of different clustering algorithms to error perturbation and the method's ability to recover a known structure depend on a number of conditions. Ward's (1963) hierarchical minimum variance method, average linkage (sometimes called group average; UPGMA) and k-means relocation, based on a sound start classification, have often been reported to be useful methods (Milligan, 1980, 1981; Morey, Blashfield, & Skinner, 1983). Promising methods based on so-called beta-flexible clustering have also been suggested (Belbin, Faith, & Milligan, 1992).

It is well-known that outliers can distort the results of many statistical analyses (e.g., of a correlational analysis). Similarly, multivariate outliers can distort the results of a cluster analysis. Based on this reason, it has been suggested for some situations that not everybody should be classified and that outliers should be removed before the classification analysis is carried out (Edelbrock, 1979; Milligan, 1980). Bergman (1988b) also emphasized that a small number of truly "unique" individuals may exist and that they should not be forced into a classification. They should instead be brought to a set of nonclassified subjects, called a "residue." In the LICUR method for classification analysis, presented later, a procedure for accomplishing this is indicated. Of course, residue subjects can be highly interesting, but they should be analyzed separately, perhaps using qualitative methods.

Longitudinal Cluster Analysis

A direct way to study individual development in terms of patterns is by exposing the subjects' complete observed longitudinal patterns to a cluster analysis. In this way, the clusters are formed in one analytical step and, it is hoped, a full account is taken of each subject's developmental pattern in forming the clusters. A related approach is to use an ordination strategy to first reduce the number of dimensions (e.g., using principal components analysis) and then perform a cluster analysis of the factor scores (e.g., Mumford & Owens, 1984). Although potentially attractive, this genuinely longitudinal approach can be problematic; for instance, it often results in heterogeneous clusters that are less useful. When only profile form is a focus, a direct longitudinal classification approach may be more useful, because less information has to then be summarized by the cluster membership variable than when both profile form and level are to be accounted for by the method. Therefore, taking into account only profile form increases the chances of obtaining homogeneous clusters in that sense. Block (1971) presented a good example of the potential of

a longitudinal classification strategy in his study of longitudinal personality types.

Cross-Sectional Pattern Analysis Followed by Linking over Time

A natural way of studying development using a classificatory approach is to first perform a cross-sectional cluster analysis at each point in time separately and then link the results; this is most frequently accomplished by cross-tabulating results between adjacent time points. For this purpose, different methods can be used; the choice of method should, of course, be tailored to the specific case.

There is also value in a standard method that is reasonably robust, can be applied in a variety of situations, and can serve as a reference method. For this purpose, Bergman (1998) developed a cluster analysis-based procedure, LICUR (Linking of Clusters after removal of Residue), for cross-sectional classification, after removal of a residue, followed by the linking of results between measurement occasions. It is suitable for interval-scaled data in situations when both the form and level of the profile are of relevance, and when an important goal is to obtain homogeneous clusters. The key aspects of LICUR are as follows:

- First, at each measurement occasion separately, a residue of subjects (outliers) is identified according to criteria defined beforehand. They should not be classified together with the others and are removed as a residue for separate analysis (often 1% to 3% of the sample are categorized in this way). The size of the residue can be a valuable indicator of the “classifiability” of the sample, with a large residue perhaps indicating that there is no clear classification structure to be found.
- Then, on each measurement occasion separately, a cluster analysis is performed using Ward’s hierarchical cluster analysis method as the standard option, and the cluster solution with the optimal number of clusters is chosen. Four different criteria are used to guide this decision.
- If the hierarchical property of the cluster solution is vital, each cross-sectional analysis stops here. When there is a very strong focus on obtaining as homogeneous clusters as possible, the Ward cluster solution is used as a start solution in a k-means relocation cluster analysis. In this procedure, the objects are relocated to maximize the explained error sum of squares and, hence, cluster homogeneity.
- In the last step, the results of the cluster analyses carried out at each age separately are linked by cross-tabulating adjacent classifications and tested for significant types and antitypes of cluster membership combinations, using

exact cell-wise tests (Bergman & El-Khoury, 1987). In this way, we can identify developmental trajectories, defined at each measurement occasion as a typical pattern, that occur more frequently or less frequently than expected by chance.

By comparing the cluster solutions at the different ages, we can study *structural stability and change*. By studying the cross-tabulations across age, we can study *individual stability* (which is shown if it is a significant type to belong to approximately the same cluster at both ages) and *individual change* (which is shown if it is a significant type to move from one cluster to another).

In our opinion, LICUR is a robust and basic method that is applicable in a large number of settings. For instance, it can also be used when different variables are measured at the different measurement occasions and during periods of dramatic developmental shifts. For a more full description of LICUR, the reader is referred to Bergman (1998) or Bergman et al. (2003).

An Empirical Example of a Person-Oriented Classification Approach

In the following, an empirical example is given of a person-oriented approach for studying the development of boys’ externalizing problems. It builds mainly on findings reported in Bergman and Magnusson (1991, 1997), and the example illustrates mainly the use of the LICUR procedure. For a description of the background to these studies and for technical details, the reader can refer to these sources.

The data were taken from the longitudinal research program Individual Development and Adaptation (IDA; Magnusson, 1988). Depending on the analysis, the sample size varied between $n = 517$ and $n = 540$. At age 10 and age 13, the same six variables were measured: Aggression, Motor Restlessness, Lack of Concentration, Low School Motivation, Poor Peer Relations, and Low School Achievement. All variables were scaled on a quasi-absolute scale, with 0 = absence of a problem, 1 = tendency to a problem, 2 = presence of a problem, and 3 = pronounced problem. Each boy’s profile of values in these six variables constituted the basic unit of analysis. For instance, the profile “000000” at age 10 would indicate a boy with no problems at that age, and the profile “022202” would indicate a boy with a low school motivation syndrome. At adult age, information from official records was used. The presence or absence in official records for psychiatric care was noted. In addition, the presence more than once, the presence once, or the absence in official records for criminality and alcohol abuse was noted.

First, a cross-sectional analysis was carried out at age 10. The first step in this analysis was to identify a preliminary residue of nine boys with unique value profiles. They were removed before further analyses were undertaken. The second step was to use Ward's hierarchical method to obtain a nine-clusters solution according to the LICUR criteria. This solution was used as a start classification in a relocation analysis that was undertaken to further improve cluster homogeneity (the final explained error sum of squares was 72%). Three subjects that did not fit any cluster were removed in this step, increasing the size of the residue to 12 subjects. At age 13, the same analytic procedure was used, resulting in an eight-clusters solution with an explained error sum of squares of 71% and with eight subjects being identified as residue subjects. In Figure 21.2, we give the means in the variables in the profile for each cluster at age 10, with the cluster means for the best matching cluster at age 13 drawn in the same picture. Please note that the matching is a forced, pairwise matching; therefore, it is possible that a cluster at age 10 must be paired with the next best matching cluster at age 13, if the best matching cluster is better matched to another age 10 cluster and, hence, already "occupied."

From Figure 21.2, we can see that six of the age 10 clusters showed structural stability and an additional two clusters showed partial stability. Cluster 2 at age 10 had no matching cluster at age 13 but is rather similar to Cluster 4 at that age. The picture is one of considerable structural stability across these two ages. To summarize, the following stable typical patterns were found: a pattern showing a complete lack of any adjustment problems, one characterized by only a tendency to Motor Restlessness and no other problems, one characterized by Poor Peer Relations and no other problems, one characterized by Low School Achievement and no other problems, a low school motivation syndrome, and a syndrome characterized by severe generalized conduct problems. The conclusion is that most typical patterns of externalizing problems that appeared at age 10 also emerged at age 13.

The next question is, of course, whether the structurally stable typical patterns also exhibited individual stability. Do boys tend to stay in the same type of cluster at both ages? Are there also significant movements from one cluster to another across ages? Following the LICUR paradigm, a cross-tabulation of cluster membership between age 10 and age 13 was carried out and translated into a summarizing LICUR figure. Bergman and Magnusson (1991) report this LICUR figure. The essence of those results is that all the structurally stable typical patterns listed earlier also showed significant individual stability.

For the problem clusters it was, depending on the cluster, 2.2 to 7.6 times more likely than expected by chance that they would end up in the same type of cluster 3 years later. (For a review of these results, the reader is referred to Bergman and Magnusson, 1991.) To comment on just one typical pattern at age 10: Belonging to the most severe problem cluster (Cluster 9) entailed a very high risk for later severe problems at age 13. There were significant streams both to Cluster 8 at age 13, that is, the most severe multiproblem cluster at that age, and to Cluster 6 at age 13, that is, the low school motivation syndrome. No boy completely lost his adjustment problems and moved from Cluster 9 at age 10 to Cluster 1 at age 13. This raises the question of whether this very high risk also operates over a longer time period into adulthood. The results presented next shed some light on the matter.

Now we address the analysis of the adulthood data. For the purpose of this study, we had information for three variables at adult age: Criminality (trichotomized), Psychiatric Care (dichotomized), and Alcohol Abuse (trichotomized). These variables were analyzed using the CFA technique, described in a later section, and the results are reported in Bergman and Magnusson (1997). We have three possible values in each of Criminality and Alcohol Abuse and two in Psychiatric Care. That renders a total of $3 \times 3 \times 2 = 18$ configurations to study. Five significant types were found. They were either characterized by both Criminality and Alcohol Abuse but not Psychiatric Care (three types) or by all three problems occurring together (two types). The last two types were extremely clear, with observed frequencies almost 20 times larger than expected. It is apparent that such problems strongly come together at adult age. For a further discussion, the reader can refer to Magnusson (1988). Based on this information, Bergman and Magnusson (1997) constructed a classification of adult adjustment problems into five categories: (A) No problems, (B) Criminality only, (C) Psychiatric Care only, (D) Criminality and Alcohol Abuse, and (E) a mixed group (those that did not fit into the other categories).

It is of interest to study how childhood adjustment problems are related to problems in adulthood at a pattern level. This can be done using the LICUR procedure and are reported by Bergman and Magnusson (1997). The basic LICUR rationale was followed so that the eight typical patterns at age 13 were related to the five categories of adult problem combinations. This was done in an 8×5 cross-tabulation that is summarized in Figure 21.3 on page 863.

As shown in Figure 21.3, four strong types occurred: (1) It was more frequent than expected by chance to

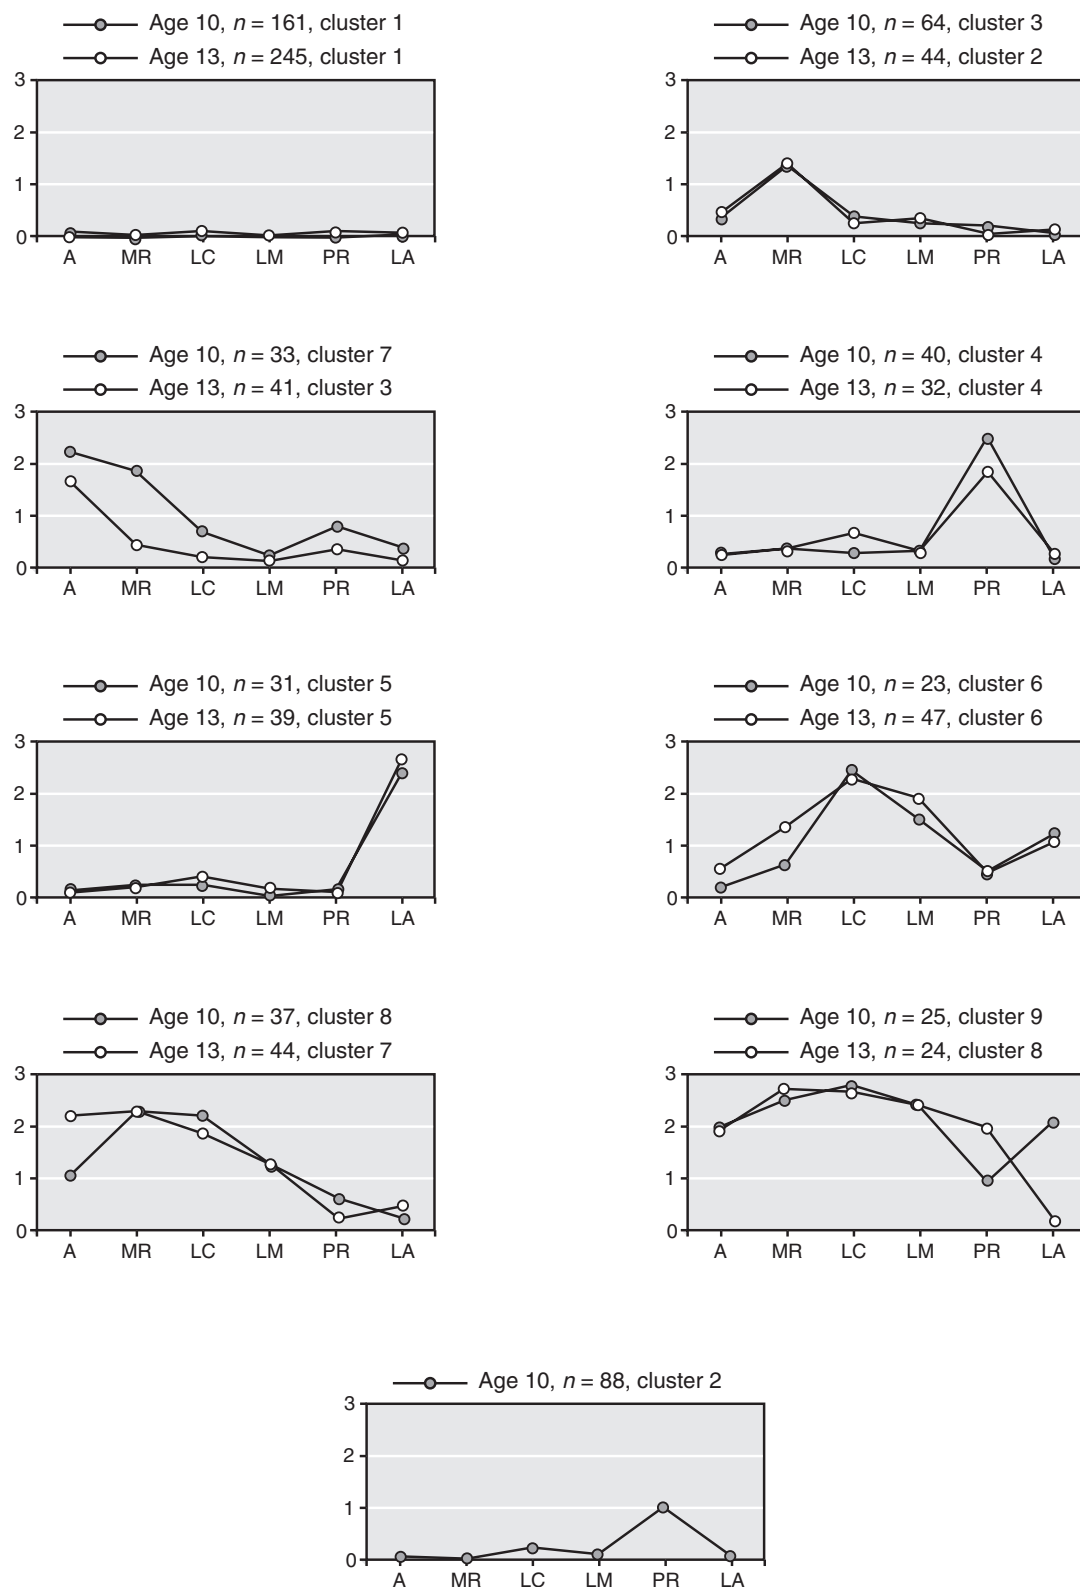

Figure 21.2 Cluster means for the cluster solutions at age 10 and age 13. *Notes:* A = Aggression; MR = Moror restlessness; LC = Lack of concentration; LM = Low school motivation; PR = Poor peer relations; and LA = Low school achievement.

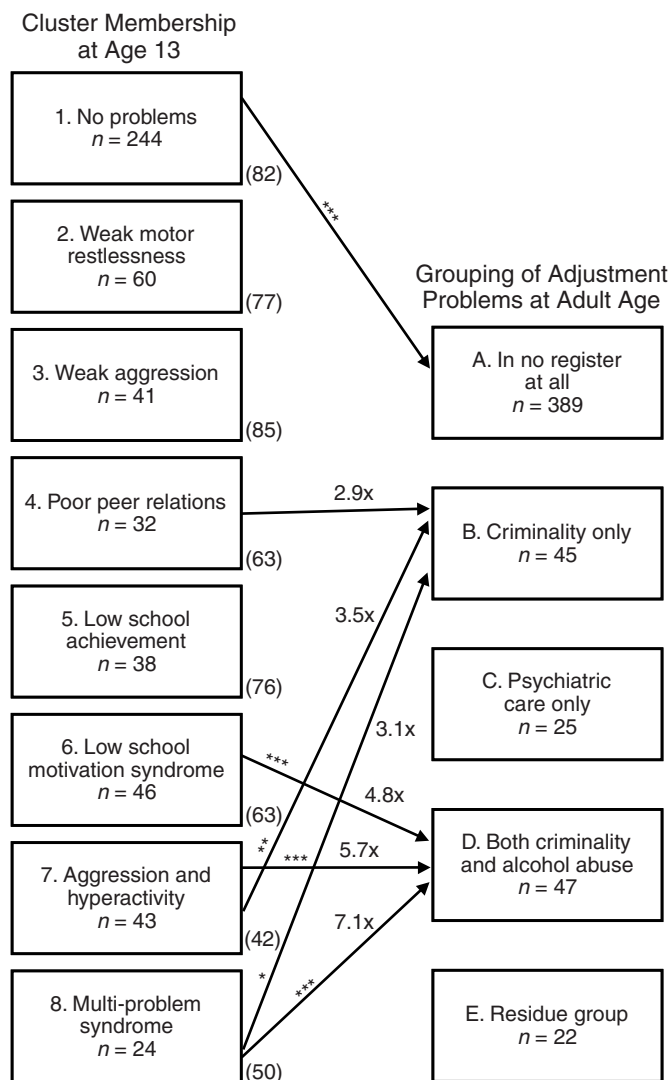

Figure 21.3 Significant longitudinal streams between age 13 and adult age. Figures on arrows indicate how many times more frequent the pattern combination is from what is expected from the development of the No Problems cluster. Figures within parentheses indicate the percent of the cluster that are found in the normal group of adult age. Only significant streams are presented and an exact one-tailed hypergeometric test was used. Notes: * $p < .05$, $p < .01$, $p < .001$. Reprinted with permission from “A Person Oriented Approach in Research on Developmental Psychopathology,” by R. L. Bergman and D. Magnusson, 1997, *Development and Psychopathology*, 9, 291–319.

belong to the “well-adjusted” group at both ages, and (2) belonging to any of the three multiproblem clusters at age 13 was strongly related to showing both Criminality and Alcohol Abuse at adult age. This risk was 5 to 7 times higher than expected by an independence model and highest for Cluster 8, that is, for the most severe multiproblem syndrome at age 13. There were also marginally significant longitudinal streams involving mainly the two most severe multiproblem clusters and Category B, characterized by Criminality only. It is also of interest to observe the *absence* of significant longitudinal streams between,

on the one hand, Cluster 2 and Cluster 3 at age 13 (weak Motor Restlessness and Aggression, respectively) and, on the other hand, any of the adult adjustment problem groups. Not even a tendency was found in this direction.

Based on these and other results, Bergman and Magnusson (1997, p. 309) write:

Seen in perspective, an overall picture emerges: At each age severe problems tend to occur together. Boys with multiple childhood problems have a much higher risk than other boys of exhibiting both criminal behavior and alcohol problems as adults, perhaps also psychiatric problems. Single adjustment

problems in childhood do not usually have strong manifestations and are not related to adult problems. Alcohol problems in adulthood rarely occur alone, while psychiatric problems occurring alone are not related to patterns of childhood externalizing problems. The conclusion is inescapable: Problems tend to occur together in syndromes. It is the severe problem syndromes in late childhood and adulthood that link up; the rest is secondary. Hence, attention should be focused on such syndromes characterizing individuals rather than on variables viewed separately.

Next, we briefly indicate a few more examples of research findings that are based on the use of person-oriented methods for analyzing the IDA data set introduced previously. This is done in order for the reader to obtain some idea of the variance of problems and methods that can be used in a person-oriented perspective. Of course, other problems could have been tackled and many other methods could have been used, some of which are discussed in this chapter. However, we must draw the line somewhere, and we chose the three following simple examples:

1. Bergman and Magnusson (1997, p. 303) proposed a hypothesis of *problem gravitation* that deals with how patterns of externalizing adjustment problems evolve: "With age there is a tendency for externalizing problem patterns characterized by just a single problem or a few mild problems to become less frequent in relation to the well-adjusted patterns and the more severe multiproblem patterns. Either the child outgrows mild problems or these become worse. New problems for initially well-adjusted children emerge less frequently at a higher age than at lower ages." One way this hypothesis was tested was by comparing the multiproblem to single problem ratio between age 10 and age 13. This ratio increased from 0.75 to 1.28. Based on this and other evidence, Bergman and Magnusson concluded that the hypothesis was supported. They also pointed out that the concept of problem gravitation is natural to study in a person-oriented perspective, but it is largely overlooked in variable-oriented research (it is *not* identical to the concept of increased comorbidity with age). As an empirical phenomenon, problem gravitation may lie hidden in many data sets, not shown by standard variable-oriented analyses and perhaps obscured by variable standardization, and so on. Once the concept is on the table it can, of course, be studied using suitable variable-oriented methods. Problem gravitation was also discussed by Stattin and Magnusson (1996) from the standpoint of the development of antisocial behavior.
2. What is the importance of a childhood variable versus the pattern it is a part of? This is an interesting question to ask when you want to understand the roots of adult adjustment problems. Magnusson and Bergman (1988) noted two things when analyzing the predictive power of boys' late childhood aggression for adult criminality and alcohol abuse: that aggression predicted adult problems, and that aggression often appeared in a value pattern of many externalizing problems; it exhibited comorbidity with, especially, other conduct problems. This is nothing new. They then posed the question of whether it is the multiproblem pattern that is behind the relationship aggression showed with adult adjustment problems. That is, aggression in itself is perhaps of no importance for predicting criminality. It is only because it is a rather good indicator of a multiproblem pattern that the relationship appeared. This was tested by removing those that belonged to a multiproblem pattern and then recalculating the relationship between aggression and criminality/alcohol abuse. The relationship then vanished, supporting the conclusion that aggression in itself was of no importance. This issue has been analyzed in more depth by Bergman and Magnusson (1997) and Stattin and Magnusson (1996).
3. It is probably fair to say that in developmental research, the focus is on finding things that go together and explaining the common developmental paths. However, when discussing Lienert's concept of antitype, Lienert and zur Oeveste (1985) pointed out that what does *not* occur can also be informative. Why do certain configurations occur less frequently than expected by chance? When Bergman (1988b) discussed the residue concept, he pointed out that unique cases tell us about what occurs rarely, and that this knowledge may be of theoretical relevance. You can formulate hypotheses of value patterns that should not occur according to your theory and test them using his Residue Analysis (RESIDAN) approach. This line of thinking was also developed by Bergman and Magnusson (1997), who coined the term "white spots." They reported results indicating that certain important adjustment problems rarely occurred alone (e.g., lack of concentration and being repeatedly registered for alcohol abuse), and they also discussed questions about causal mechanisms. The concept of white spots is further elaborated in the discussion part of this chapter.

Studying Development through an Age-Invariant Classificatory Grid

Considering individuals as dynamic systems studied in an interactional paradigm, Bergman and El-Khoury (1999)

stressed the usefulness of the concept of *i-state* from their classificatory perspective. They defined *i-state* as a specific subject's profile of scores at a specific point in time. In other words, they drew a parallel between the standard person-oriented basic unit of observation and the corresponding concept in dynamic systems terminology, that is, the state of the system at a given time. A dynamic systems perspective suggested that it might be interesting to identify the typical *i-states* for a sample of subjects across time. These would, in a way, correspond to attractors in a dynamic system. The first task is then to identify the typical *i-states* that exist *irrespective of the time points they refer to*. This is done in *i-states-as-objects* analysis (ISOA) by considering each *i-state* as a "subindividual" and then carrying out a classification analysis for all *i-states*. Hence, the number of objects in this analysis is the number of time points \times the sample size. To carry out ISOA, you must have longitudinal data with the same variables measured at the different points in time so that the value profiles are comparable across age. The result of the first step of the ISOA analysis is a set of typical *i-states* (= classes of value profiles) that occur in the sample, disregarding the age at which they occur. The relative frequencies of the different typical *i-states* are then compared between ages to study structural stability and change.

In a second step of ISOA, it is noted, for each subject, what typical *i-state* he or she belongs to on each measurement occasion. In this way, each subject's sequence of *i-states* is established. These sequences are further analyzed to study individual stability and change.

In certain situations, ISOA can extract more information from the data than conventional methods can, especially when there are many measurement occasions. However, the applicability of ISOA is normally restricted to rather short periods of development as it must be assumed that, in principle, the same typical *i-states* occur at all measurement occasions, although with varying frequencies.

Partial Classification in a Developmental Setting

Earlier, we pointed out that we cannot always expect that every subject belongs to one of a small number of mutually exclusive classes or clusters, and we argued for the usefulness of removing multivariate outliers before the classification analysis is carried out. These normally constitute just 1% to 3% of the sample. However, for some data sets, one might not want to assume that anything like a complete classification structure exists. On the other hand, it might be reasonable to believe that a proportion of the sample belongs to one of a small number of typical patterns, with the rest of the sample exhibiting no clear classification struc-

ture and being best regarded as "noise." This line of reasoning is suggested by an analogy to results from studying complex dynamic systems, where one often finds a number of attractor states but also other states, some of which can be the result of a chaos-generating mechanism.

Against this background, Bergman and El-Khoury (2001) indicated a method, types-at-focus (TYFO), in which they attempted to find dense points in a longitudinal data space. When applying TYFO, it is assumed that a profile of interval-scaled variables is the basic unit of analysis and that a classification of (almost) all subjects' profiles is unrealistic. On the other hand, it is assumed that a partial classification of "core subjects" is possible, with each of the core subjects belonging to one of a small number of homogeneous groups on each measurement occasion. The aim of the analysis is to find and replicate these dense points and then to provide information on the core subjects' stability and change across time with regard to belonging to these dense points.

Classifying Sequences of States

I-state sequence analysis (ISSA; Bergman, 1995) is a truly longitudinal classification method for studying the development of individual patterns. It is based on a person-oriented framework and uses concepts and ideas taken from the study of nonlinear dynamic systems. As in ISOA, a basic concept in ISSA is the *i-state*, that is, an individual's configuration of values in the relevant variables at a specific point in time. Intraindividual *i-state* sequence development is first described, and every subject is classified as being characterized by belonging to one of the following five general classes of *i-state* involvement: fixed *i-states*, semistable *i-states*, directed *i-states*, transient *i-states*, or irregular *i-states*. Then the typical states in each class that exist in the sample are searched for, and, finally, interindividual development is studied by analyzing the sequences of typical *i-state* classes the subjects belong to.

Both a general procedure, which can be tailored by the researcher according to his or her needs, and a standardized procedure exist. The empirical results that have been obtained for a test data set and a replication data set are encouraging. In some situations, ISSA is a viable alternative to other types of descriptive longitudinal classification methods, and it may provide a more robust classification than these methods do. However, ISSA appears to be optimal for situations when development is studied over limited time periods without dramatic shifts in basic characteristics of the studied system.

Latent Transition Analysis

Collins and Wugalter (1992) presented a rationale and a program called latent transition analysis (LTA) for the developmental classification of discrete latent variables. LTA builds on latent class analysis (LCA), where a discrete latent variable is inferred from manifest discrete variables. The cases are described by the values in a number of categorical variables and the covariations among these variables are studied. A nonobserved latent categorical variable is then searched for, the values of which will decompose the original data set into classes in such a way that all systematic relationships between the variables vanish (the assumption of local independence). If such a variable is found, it is said to “explain” the relationships.

Latent class probabilities and conditional probabilities are two types of probabilities in LCA. The relative sizes and the number of latent classes reflect the latent class probabilities. With regard to conditional probabilities, it should be kept in mind that the classes are not deterministically characterized in the same sense that clusters are in cluster analysis. Rather, a case is regarded as belonging to a class if its conditional probability of belonging to that class is high, depending on the subject’s response pattern.

In LTA, a model can be constructed with an array of latent classes representing latent status at a given time. The latent statuses are used to construct what Collins and Wugalter (1992) call stage-sequential dynamic latent variables. Transition probabilities for the latent statuses between adjacent time points are estimated in the model. Using LTA, different models about pattern development can be tested and the model can handle certain types of measurement errors. After reviewing LTA, Bergman et al. (2003) suggested that the power of LTA to reject a “bad” model might be low for small to medium sized samples unless a “strong” model can be tested (i.e., a model with almost all parameters fixed). Nevertheless, the LTA approach can be highly relevant and has several attractive features, two prominent ones being that it allows for model testing and that its model parameters can in some situations nicely mirror a theoretical person-oriented model.

Meehl’s Taxometric Approach

An important classificatory approach is given by Meehl’s taxometric procedures. The reading of his work is educative for anyone interested in searching for natural categorical entities (see also Gangestad & Snyder, 1985). Meehl (1992) makes the distinction between what he calls a taxon (a “natural class”) and an arbitrary class, and he discusses different procedures for finding and verifying a taxonomic

structure. Meehl is skeptical of the use of cluster analysis for taxometric purposes: “The cluster methods are at best viewed as ‘plausible’ numerifications of the intuitive notion of clumping in the phenotypic descriptor hyperspace” (p. 130). The essence of his argument is that certain other types of classification approaches than cluster analysis have larger chances of finding and validating a “natural” classification structure.

The contrast of his thinking to the principles presented in earlier sections is not as large as it may at first seem. From our perspective, we see the complete procedure of finding a sound classification system as containing two steps. The first is to establish a trustworthy classification in the sense that it is reliable and nonarbitrary. This is similar to Meehl’s emphasis that the communalities and differences in classification results should be studied using different procedures. The second step is to study the usefulness and validity of the obtained trustworthy classification, and in doing that, the results will either prove or disprove that the classification has produced what Meehl calls taxa. This similarity will become more obvious from the brief description of his procedures.

Meehl especially advocates the use of his own latent class procedure where he applies a system of “coherent cut kinetics” (Meehl & Yonce, 1992; see also Waller & Meehl, 1998) to establish taxonicity, estimate parameters of the latent model, and assign subjects to the appropriate class. For instance, Meehl (1992) mentions two procedures for accomplishing this: maximum covariance (MAXCOV) and mean above minus below a cut (MAMBAC). However, the power of these procedures to establish taxonicity is unclear (see Maraun, Slaney, & Goddyn, 2003).

The term coherent cut kinetics refers to a procedure where one creates value intervals for an input variable and then examines the behavior of other variables in the different intervals. This behavior, among other things, gives important information about the taxonicity of the data set under study. Meehl (1992, p. 136) summarizes his procedures as follows:

We hypothesize a certain latent structure underlying our data (i.e., that there is a taxon group and a complement group) and we know that if we are correct certain quantitative relations in the data are entailed by others. We examine these several relations to see if they obtain, as they will if our conjecture about the latent structure is correct.

In connection with presenting his procedures, Meehl (1992) pays attention to the issue of how we decide whether we should trust the results produced by a taxometric proce-

ture. This issue is complex. First, different procedures or operations on the data set under study should be used to show that there is a convergence of evidence. He indicated a number of ingenious procedures for evaluating the validity and general usefulness of a classification method. A point raised by Meehl is the importance of discriminating between two purposes one might have with a classification: to show the existence of types (taxa, in Meehl's terminology) and to assign subjects to the appropriate class. Quite frequently, these two purposes are not kept apart, and it is not always realized that a classification can be successful with regard to the first purpose but not with regard to the second one.

A Person-Centered Strategy for Linking Life Histories to Outcomes

There is a tension between, on one hand, the need to account for individual life trajectories in a case-wise manner, where the richness of the individual life is retained, and, on the other hand, the frequent need to study fairly large samples and compare results across individuals. An innovative way of tackling this problem is an approach developed by Singer and coworkers (Singer, Ryff, Carr, & Magee, 1998). The basic principle of this approach is that information available in a longitudinal study (including quantitative variable-oriented information) is used to create detailed descriptions of individual lives, and from these descriptions generalizable characteristics are found and compared between outcome groups. They present principles for the organization and interpretation of life history information. In their empirical example, Singer et al. used data from the Wisconsin Longitudinal Study and analyzed life histories of what they call "resilient" women (having a history of depression but at the time of follow-up reporting a high level of well-being). In a step-wise fashion, first narratives of life histories were written, and then they were reviewed for communalities and transformed into more generic descriptions. Finally, the distinguishability in them between the resilient and three other mental health groups was tested.

Hongxin, Brooks-Gunn, McLanahan, and Singer (2000) suggested an extension and exemplification of this approach in the context of child development. They discussed the issue of bringing back the person into developmental studies, using the phrase "studying the real child rather than the ideal child" (p. 393). In this discussion, they gave good arguments for the usefulness of the narrative approach, of which they provided an empirical example. In the example, they used longitudinal survey

data from the Child Supplement to the National Longitudinal Survey of Youth. Their aim was to study the multiple pathways that subgroups of children follow to arrive at either an outcome indicating resiliency to adversity (adversity defined as having a teenage mother) or an outcome indicating vulnerability to adversity. The analytic strategy included five steps:

1. The construction of narrative stories for a subsample of cases from each of the two outcome groups.
2. Identifying similar and distinct pathways within each group.
3. Response vectors that mirror the developmental process according to the organizing principles.
4. Summary representations of developmental experiences.
5. Tests of distinguishability to study whether the developmental pathways differ between the two groups.

Distinct differences in the pathways were found between the resilient and the vulnerable group, and the results provided a wealth of interesting information that contributes to the understanding of the development of persons "as wholes" in a way that cannot be accomplished by an ordinary variable-oriented approach.

Configural Frequency Analysis

Configural frequency analysis (CFA; Lienert & Krauth, 1975; von Eye, 2002) allows one to identify *patterns of variable categories*, also called *configurations*, that are observed more often (types) or less often (antitypes) than expected based on some chance model. If these discrepancies are significant, then configurations reflect local associations, that is, associations that exist only in particular sectors of the variable space (Havránek & Lienert, 1984).

Cross-classifications can be analyzed from both variable-oriented and person-oriented perspectives. Variable-oriented analysis of cross-classifications focuses on three kinds of research questions (Goodman, 1991):

- What is the joint frequency distribution in the table?
- What is the association structure of the variables that span the cross-classification?
- What is the dependency structure of the variables that spans the cross-classification?

Each of these questions can be answered using log-linear modeling and related methods, for example, logistic regression.

In contrast, under a person orientation, researchers would ask such questions as:

- Can the c configurations in the table—these configurations are defined by the c cells of the table—be classified in $g < c$ groups such that within-group similarity is maximized while between-group dissimilarity is also maximized?
- Do individual cells or groups of cells contain fewer or more cases than expected based on some *chance model* (also called *base model*; von Eye, 2002)?

The first of these questions can, of course, also be answered using methods of clustering or latent class analysis. The method of choice for the second question is CFA. This second question comes in many different forms. The following are four sample questions (cf. von Eye, 2002):

1. *How do the observed frequencies compare with the expected frequencies?* As will be explained below, the first step of a CFA application involves selecting a chance model, also called a *base model*. This model specifies the expectations under which we inspect the observed frequencies. For example, one can create a base model that posits that no variable interactions of whatever order exist. If a configuration violates this assumption, then an interaction must exist, at least locally. Other base models posit that first-order associations (parallel to zero-order correlations) exist. Violations of this assumption point to the existence of second- or higher-order associations, also at least locally. Selecting a base model is of utmost importance in CFA because decisions as to whether or not particular configurations were observed more or less often than expected depend on the base model. It is a frequent result of CFA that configurations are identified as types under one base model, but remain inconspicuous or even constitute antitypes under some different base model.
2. *Do two or more existing groups differ in their multivariate frequency distributions?* Here again, several base models are conceivable. In each case, however, the main question is whether group-specific associations or dependency structures exist. If such a structure is group-specific, then at least one of the groups under study will show more (or fewer) cases in a particular configuration than expected based on the assumption of, for instance, independence of groups, and these types should differ between groups.
3. *What are the characteristics of changes in interaction patterns over time?* To answer this question, a base model proposes, for instance, that the interaction pattern remains unchanged over time. In addition, one can ask whether changes are group-specific, thus combining group comparisons with longitudinal CFA.

4. *Can predictor-criterion relationships be identified at the level of configurations?* Here, we ask whether particular predictor-criterion patterns occur more or less often than expected. If such a pattern is observed more often than expected, then one can conclude that the predictor configuration allows one to predict the criterion configuration. If there are fewer cases than expected, then one can conclude that this predictor configuration allows one to predict that the companion criterion configuration will not be observed (or will be observed less often than expected). Depending on the nature of the data under study, this latter situation may open the doors for the conclusion that a particular predictor pattern prevents the companion criterion pattern from occurring, a result that can be of importance in intervention research.

Configural Frequency Analysis Requires Five Steps

When performing CFA, five steps are required, with their corresponding decisions. In the following paragraphs, these five steps are introduced (for more detail, see, e.g., von Eye, 2002; von Eye & Niedermeier, 1999).

Step 1: The Selection of a Base Model. This is most important because the base model is the background in front of which CFA types and antitypes are interpreted. The base model reflects the theoretical assumptions that carry an analysis. If the base model does not correspond to these assumptions, then types and antitypes cannot be interpreted without problems. Changing the base model can have the effect that new types and antitypes emerge or existing types and antitypes disappear. Most CFA base models can be expressed as log-linear models. The comparison of the estimated values computed from this model with the corresponding observed frequencies leads to the decision of whether a configuration constitutes a type or an antitype or conforms to the prediction made by the base model.

The original model of CFA (Lienert, 1969) used the model of variable independence as its base model. This model reflects the assumption that the variables that span the cross-classification under study are unrelated to each other. They can show only main effects. If types and antitypes emerge, then associations must exist. Another well-known example of a CFA base model is that of *Prediction CFA*. The base model for this CFA variant proposes that:

- Predictors are related to each other as in a saturated model. That is, all possible associations among predictors are part of the base model.
- Criteria are related to each other as in a saturated model.
- Predictors and criteria are independent of each other.

This model can be contradicted only if predictor-criterion relationships exist. These relationships indicate that, for the configurations that stand out as types or antitypes, predictive relationships such as the ones indicated exist. If the number of types and antitypes is small, then predictive relationships exist only in parts of the multivariate data space (as opposed to the entire space, as is often assumed in the analysis of continuous variables).

Two or multigroup CFA is a special case of Prediction CFA. This model of CFA proposes that (1) the variables that are used to predict group membership are related to each other as in a saturated model, and (2) these variables are unrelated to the variable that denotes group membership.

A few CFA base models exist that are not log-linear (von Eye, 2002). For example, in certain contexts, events and configurations can come with a priori determined probabilities. Examples of such cases include the a priori probabilities of patterns of change in categorical variables. Other non-log-linear base models include those that take into account a priori probabilities taken from population statistics.

In either case, the selection of a base model can have major implications for the interpretability of CFA results. Therefore, researchers typically take great care in the specification of base models and often reanalyze their data using different base models to determine the effects of different choices of base models. The specification of base models follows the three rules proposed by von Eye and Schuster (1998):

1. CFA base models are parsimonious. Thus, they contain as few terms as possible, and these terms are of the lowest possible order.
2. CFA base models take sampling schemes into account. This rule implies that the margins of variables that are observed under a product-multinomial sampling scheme must be reproduced by the base model.
3. The most important of the three rules is the third: CFA base models must be specified such that only one reason for deviations between observed and expected cell frequencies can exist. For example, the CFA base model that takes only main effects into account can be contradicted only if associations exist. The base model for Prediction CFA can be contradicted only if predictor-criterion relationships exist, and so on.

Step 2: The Concept of Independence. Most base models of CFA incorporate some concept of independence. There are two aspects of independence in CFA. The first of

these is that many base models posit some type of independence among variables or variable groups. This applies even if associations of first or higher order are part of the base model. In these cases, independence refers to higher-order associations.

The second aspect, and this is the one at issue when a concept of deviation from independence is selected, concerns the type of deviation from independence. Typically, deviations from independence are cast in terms of deviance residuals, that is, the difference of estimated expected cell frequencies from observed cell frequencies, or standardized versions of this discrepancy measure. In addition, the marginal frequencies are typically taken into account when the discrepancies between the estimated expected cell frequencies and their observed counterparts are evaluated. The measures that depict the relative magnitude of the discrepancies between the estimated expected and the observed cell frequencies are thus termed *marginal-dependent* (Goodman, 1991; von Eye & Mun, 2003). Sample measures include the well-known Pearson χ^2 -component and the standardized residual, a *z*-measure. However, there exist measures of deviation from independence that do not take the marginal frequencies into account. These measures are termed *marginal-free*. Examples of such measures include the log-odds ratio. Von Eye, Spiel, and Rovine (1995) proposed using marginal-free measures for two-sample CFA. The authors showed that type and antitype patterns depend on whether marginal-free or marginal-dependent measures are used. When the marginal frequencies differ dramatically and associations are strong, marginal-free measures may be more appropriate (see also von Eye & Mun, 2003) because they are sensitive to interactions without taking main effects into account. This is of importance in particular for two-sample CFA and Prediction CFA.

Step 3: The Selection of Significance Tests. This issue has been widely discussed in the development of CFA methods. This discussion has addressed issues of statistical power, the α - and the β -errors, the relative frequencies of types and antitypes, the distribution of the various measures, the assumptions that need to be made when using a measure, the small sample performance of measures, the sensitivity of measures to different sampling schemes, the performance of measures under various marginal distributions, and the performance of measures in tables of varying sizes (von Eye, 2002, 2003; von Eye, Lautsch, & von Weber, 2004; von Eye & Mun, 2003). In the following sections, we present a selection of three measures that (1) perform well under many

conditions, (2) display a number of other desirable characteristics, and (3) differ in the assumptions they require users to make. Let m_i be the estimated expected frequency of Cell i and f_i the corresponding observed frequency.

The first test that was proposed for use in CFA is the Pearson χ^2 -test:

$$\chi^2 = \frac{(f_i - m_i)^2}{m_i}$$

This statistic has the following characteristics:

- It is nonparametric.
- It is marginal-dependent.
- It is powerful, in particular when samples are large.
- It is, for large samples, asymptotically distributed as the χ^2 with $df = 1$.
- It requires large samples to keep α and χ low.
- It needs large samples to reach a power of $p = .8$.
- It tends to detect more types than antitypes when samples are small.
- It tends to detect more antitypes than types when samples are large.

In addition, it is easy to calculate.

The second measure is Lehman's (1981) asymptotic hypergeometric test. The formula for it is rather complicated and is omitted here. The test has the following characteristics:

- It requires sampling to be product-multinomial.
- It is marginal-dependent.
- It is most powerful, regardless of sample size.
- It approximates the normal distribution only for very large sample sizes; for smaller sample sizes, the statistic can suggest nonconservative decisions.
- It requires large samples to keep α and χ low.
- It needs only small samples to reach a power of $p = .8$.
- It detects equal numbers of types and antitypes for 2×2 tables and approximately equal numbers of types and antitypes for large samples in tables of different sizes than 2×2 .
- It can be applied only in first-order CFA.

The third test to be discussed here is the binomial test. Let the estimated probability for Cell i be $p = m_i/N$ and $q = 1 - p$. Then, the exact tail probability for the frequency found for Cell i is

$$B(if) = \sum_{i=f_i}^N \binom{N}{i} p^i q^{N-i}$$

where N indicates the sample size. This test has the following characteristics:

- It is nonparametric.
- It is exact.
- Although this test is exact, it can be conservative. Typically, the probability p is estimated from the data. Therefore, it can be closer to the data under analysis than if it were known from the population. If p is closer to the data than should be, discrepancies will be perceived as smaller, and statistical decisions will be conservative.

There exist many more tests that are suitable for CFA. These tests allow the researcher to take into account a large number of assumptions and data characteristics. Unfortunately, recent simulations have shown that many of the tests, in particular the asymptotic tests, perform poorly under CFA conditions, that is, when the cell probability p is small (von Eye, 2003). Therefore, the binomial test is typically recommended. The asymptotic tests perform well mostly for very large samples.

Step 4: The Identification of Types and Antitypes in CFA. This involves two steps. The first is the application of a significance test. The second concerns the protection of the a priori selected significance threshold α . As is well-known, the significance threshold is guaranteed only for the first of a series of tests on the same data. CFA almost always involves inspecting several or even all configurations to determine whether they constitute types or antitypes. CFA is thus a method that involves *multiple testing*. If multiple tests are performed at some level α , then the risk of committing an α -error (Type I error) is not equal to α . Rather, if one takes a risk of size α multiple times, the overall risk can be much greater. This applies even if the tests are independent of each other. Taking the risk of rejecting one or more true null hypotheses is known as *capitalizing on chance*.

This risk is exacerbated when tests are dependent. In CFA, tests are dependent because they are performed on cells of the same contingency table. Von Weber, von Eye, and Lautsch (2004) showed that the magnitude of this risk depends on the size of the table. In 2×2 tables, already the result of the second type/antitype decision is completely determined by the result of the first decision. In larger tables, this dependency is smaller, but it is always present.

Two methods of protecting the a priori determined significance level have been developed. The first method (Bonferroni correction) keeps the protected, also called the *adjusted* significance level, α^* , constant for each test performed. The second method allows one to take into account (1) the number of tests already performed, (2) the total number of tests, (3) dependency patterns, and (4) whether the tests that were already performed led to rejections of null hypotheses. As one can imagine, the method that keeps the adjusted α -level constant suggests more conservative decisions, often already for the first test. The methods are reviewed in von Eye (2002).

In CFA applications, protection of the significance level is routine. One implication of this procedure is that only extreme configurations, that is, configurations that show large discrepancies from expectancy, emerge as types or antitypes. A second implication is that the sample sizes one needs for types and antitypes to emerge are often large. This applies in particular when the cross-classification under study contains many cells.

This second implication may seem prohibitive. However, considering that many test statistics that are popular in CFA applications also require large samples to approximate their respective sampling distributions, one would only reluctantly trust type and antitype claims that are based on small samples and approximate tests. Therefore, large samples are preferred for protection of the nominal α -level and performance of trustworthy significance tests. Only if both conditions are fulfilled can types and antitypes be trusted.

Step 5: The Interpretation of Types and Antitypes.

This interpretation is mainly fueled by the base model used to run a configural analysis. The base model contains all variable relations that are not of interest for possibly resulting types and antitypes. Therefore, types and antitypes indicate which configurations contradict the base model. To give examples of type/antitype interpretation, consider the sample base models discussed later. Table 21.1 lists these (and one other) models and the assumptions made by them and indicates the interpretation of types and antitypes that result for these models.

As can be seen from Table 21.1, types and antitypes in CFA have conceptually different interpretations, depending on the base model selected for analysis. It is also clear that different base models can result in different patterns of types and antitypes, because they make different assumptions. These assumptions result in different design matrices for the estimation of the expected cell frequencies, and thus in different distributions of the measures used to establish types and antitypes.

TABLE 21.1 Sample Base Models of CFA, Their Assumptions, and the Interpretation of Their Types and Antitypes

Base Model	Sample Assumptions	Type/Antitype Interpretation
Zero order	No effects present in table	Types and antitypes indicate that, locally, main effects and interactions exist
First order	Only main effects exist; variables are independent	Types and antitypes indicate that, locally, variable interactions exist
Second order	Main effects and pairwise interactions exist	Types and antitypes indicate that, locally, interactions of second or higher order exist
<i>k</i> -sample CFA	Variables used to compare the groups can be associated at any level Variable that indicates group membership and variables used for comparisons are independent of each other	Patterns of variables that are used for group comparison discriminate among groups
Prediction CFA	Predictor variables can be associated at any level Criterion variables can be associated at any level	Patterns of predictor variables go hand in hand with patterns of criterion variables (types); patterns of predictor variables do not combine with patterns of criterion variables (antitypes)
Longitudinal CFA of differences	Mean differences from one observation point to the next can have main effects, but are independent of each other	Types indicate the patterns of change that are more likely than chance; antitypes indicate unlikely patterns of change

Data Example

With the following example, we show that different base models can result in different harvests of types and antitypes. The data are taken from a project on the development of aggression in adolescence (Finkelstein, von Eye, & Preece, 1994). In a sample of 114 adolescents (38 boys and 76 girls), among others, the self-rated variable physical aggression against peers (PAAP) was observed three times, in the years 1983, 1985, and 1987. In the CFA analyses, low aggression is coded 1 and high aggression is coded 2. In the following paragraphs, we subject these data, along with the variable gender, to two configural analyses. In the first, we

perform a 2-sample gender comparison. In the second, we run a first-order CFA.

The 2-sample CFA of the variables PAAP83, PAAP85, PAAP87, and Gender proceeds under the following base model:

- The variables PAAP83, PAAP85, and PAAP87 can show main effects and interactions of any order; thus, the model is saturated in these, the discrimination variables; types and antitypes cannot emerge because of differential autocorrelation patterns.
- The variable Gender can show a main effect; that is, the fact is taken into account that more girls than boys participated in this study.
- Gender and the discrimination variables are independent.

From this base model, types and antitypes can emerge only if the discrimination variables interact with Gender. If this is the case, discrimination types indicate Gender differences such that particular patterns of the discrimination variables are observed more often in one of the gender groups than expected based on the assumption of independence of discrimination variables and Gender. To identify possible discrimination types in this 2-sample CFA, we use the χ^2 -test and the Bonferroni-adjusted $\alpha^* = 0.05/8 = 0.00625$. Table 21.2 displays the results of this 2-sample CFA.

The first column in Table 21.2 indicates the configurations that are compared in pairs. For example, the first comparison pair is Configuration 1111 and 1112. These are the

boys (Gender = 1) and girls (Gender = 2) who show physical aggression levels below the sample medians across all three observation points. The second column shows the observed cell frequencies. For example, the 13 cases in Cell 1111 indicate that 13 out of 38 boys showed consistent below-the-median aggression levels. The number 14 in Cell 1112 indicates that 14 out of 76 girls also showed consistent below-the-median aggression levels. This proportion difference of .34 for the boys to .18 for the girls comes with a χ^2 -value of 3.494 and a tail probability of 0.06. This value is greater than the Bonferroni-adjusted $\alpha^* = 0.00625$. Thus, we cannot reject the null hypothesis of equal proportions. The same applies to all gender comparisons in this analysis.

We thus conclude that, based on the present results from 2-sample CFA, there are, across three observation periods during adolescence, no significant gender differences in physical aggression against peers. We now ask whether first-order CFA presents a different picture.

As was indicated in Table 21.2, *first-order CFA* assumes that the variables that span a cross-classification are independent of each other. Types and antitypes thus reflect local associations. In the present example, we ask with first-order CFA whether local associations exist and where they are located. Tests are performed at the level of individual cells. The resulting types and antitypes therefore describe individual cells instead of pairs in cells, as in 2-sample CFA. In contrast, 2-sample CFA, as performed in the previous paragraph, performs tests at the level of comparing two cells with each other.

Table 21.3 displays the results of first-order CFA. We used the χ^2 -test again, under the Bonferroni-adjusted significance level $\alpha^* = 0.05/16 = 0.003125$. We see that, because tests are performed at the level of individual cells, the number of tests in first-order CFA is twice that in a 2-sample CFA. Consequently, the adjusted α^* is more extreme in first-order CFA than in 2-sample CFA.

Table 21.3 contains in its first column the cell indices configurations. The second column contains the observed cell frequencies. These are the same as in Table 21.2. Column 3 presents the expected cell frequencies, estimated using the base model of variable independence. The fourth column contains the χ^2 -statistics, the fifth column shows the one-sided tail probabilities, and the last column indicates the significant types/antitypes after Bonferroni correction.

The χ^2 -values for two configurations are so large that their configurations constitute types. There are no antitypes. The first type is constituted for Configuration 1111. These are the 13 boys that show below-median physical aggression against peers throughout the observation phase. Only slightly over 4 boys had been expected to show this

pattern. It is interesting to note that pattern 1112 almost formed a type of girls with below-median aggression. However, the discrepancy from expectancy is less extreme for the girls than for the boys. Therefore, the type is constituted for the boys but not for the girls.

The second type is constituted by Configuration 2222. These are the 23 girls (10.15 had been expected) who indicated consistent above-median physical aggression against peers. For boys with the corresponding pattern, we see that the observed frequency is very similar to the expected one. Still, the 2-sample CFA presented in Table 21.2 suggests that the gender discrepancy is not significant. Nevertheless, the results from first-order CFA suggest that only the girls deviate significantly from expectancy for the consistent high-aggression pattern.

From the comparison of the results in Tables 21.2 and 21.3 we conclude that indeed, types and antitypes can emerge or disappear when different base models are used. In the present example, we find that gender-specific types can exist although the gender comparison does not indicate it. An explanation of such a phenomenon, which at first sight may seem implausible, can be given using Configurations 1111 and 1112. The first of these two configurations constitutes a type. More boys showed this pattern than expected. The second of these two configurations fails to show a type. However, the comparison of the observed with the estimated expected cell frequency shows that there were also more girls with the aggression pattern 111 than expected. This difference, however, was not significant. We see that, although in both gender groups, pattern 111 occurs more often than expected, this discrepancy is signifi-

cant only for boys. The gender difference is not significant because both discrepancies go in the same direction.

When looking at Configurations 2221 and 2222, we see that the differences between observed and expected cell frequencies do go in opposite directions. However, the discrepancy is still not large enough to constitute a discrimination type (the odds ratio for this comparison is 0.435, which indicates that more girls than boys show this pattern; the tail probability for this ratio is 0.025, a value near the one shown in Table 21.2; however, this value is larger than the adjusted α^*). So, again, we note that whereas a gender-specific type emerges, the gender difference is not large enough to be significant.

From these results, we see that a CFA analysis from a person-oriented perspective can yield results that go beyond what routine application of statistical methods can give us. Using a repeated measures ANOVA, we find that, overall, the amount of aggression is different for the two gender groups ($F(1, 112) = 26.41$; $p < .01$), with boys being more aggressive than girls, and we find that there is a linear trend ($F(1, 112) = 49.43$; $p < .01$) but no quadratic trend ($F(1, 112) = 0.30$). Furthermore, there is a Gender \times Linear Trend interaction ($F(1, 112) = 9.10$; $p < .01$) such that the decrease is steeper in boys than in girls. These are important results. However, this ANOVA cannot tell us that there are more boys than expected from chance who show consistent below-average physical aggression against peers, and more girls than expected who show consistent above-average physical aggression against peers. We thus conclude that data analysis can fruitfully be undertaken from both the variable orientation and the person orientation. In many instances, the two approaches yield complementary results.

One may wonder how this result may be interpreted. We found that boys are more aggressive, yet the pattern that was found more often than expected was that of consistent low aggression. For girls, who are less aggressive, the type pattern was that of consistent high aggression. This seemingly contradictory result can be explained as follows. ANOVA is sensitive to mean differences and found the expected gender difference. In contrast, repeated-measures CFA, as performed for Table 21.3, is sensitive to particular patterns of autocorrelation. Thus, although boys are more aggressive than girls, there are more boys than expected who show consistent low levels of aggression.

Accordingly, although girls are, in general, less aggressive than boys, there are more girls than expected who show consistent high levels of aggression. Both of these groups would have remained undetected by routine application of ANOVA. We thus conclude that person-oriented

research can yield results that are hard to find from a variable-oriented perspective.

Studying Individual Trajectories

When information is available for a variable from many points in time, we talk about each individual having a trajectory of values. The study of individual trajectories can be a focus of interest. During the past decades, a variety of methods has been advanced for the purpose of studying both average trajectories and individual variation in trajectories. Two classes of methods within this framework are latent growth curve analysis (McArdle & Epstein, 1987; Muthén, 1989) and hierarchical modeling (Bryk & Raudenbush, 1992). Such methods can be highly useful but, from a more strict person-oriented perspective, focusing on typical patterns or natural classes, they are not the first choice because in their basic formulations they assume continuous variation. Nagin (1999) presented an interesting approach for studying trajectories that considers the possibility of distinct groups of individuals with different trajectories. The approach can handle three types of data—count, binary, and psychometric scale data—and for each type of data, probability distributions are proposed. The method can identify and test for a distinctive number of typical trajectories, estimate the proportion of the population that belongs to each trajectory group, and relate group membership probabilities to individual characteristics.

Nagin and Tremblay (2001) have extended the group trajectory method to handle the simultaneous study of developmental trajectories for related series of measurement in two variables. The authors point out that this approach can be useful for the study of comorbidity and heterotypic continuity. They give two empirical examples. First, the comorbidity of hyperactivity and physical aggression is studied; second, the heterotypic continuity between opposition and property offending is investigated. Based on their models, they show that the interpretation of marginal, conditional, and joint probabilities of membership in a trajectory group can be highly informative.

The extension to handling two different but related variables is useful because it enables the researcher to link the developmental trajectory of two different characteristics in a person-oriented framework where typical trajectories are a focus. Nagin and Tremblay (2001) point out that they regard the groups as an approximation of an underlying continuous process. The method allows for fuzziness in group membership by giving it a probabilistic framework. This approach does not build on the latent variable concept as it

is commonly interpreted, and it does not explicitly handle errors of measurement. Of course, from our person-oriented perspective, it is a limitation that the method cannot handle multivariate developmental trajectories; that is, developmental trajectories of patterns of more than two variables cannot be studied. It is hoped that an extension of the methodology to this more general situation will follow in the future.

STRUCTURAL EQUATIONS MODELING AS A METHOD FOR PERSON-ORIENTED ANALYSIS

We start this section with a review of the concept of *dimensional identity*. This is a concept that has been elaborated by von Eye and is defined as follows: “A set of variables can be defined as displaying dimensional identity if the interrelations among the variables in this set remain unchanged across the levels or categories of other variables” (von Eye & Bergman, 2003, p. 554). This identity can be specified at different levels, for instance, with regard to mean structures and correlation structures. Only if there is dimensional identity can variable-oriented methods studying the whole population be justified (see also Schmitz, 2000, on conditions when the aggregation of individual processes is warranted). Otherwise, person-oriented methods are appropriate. From this perspective, one way of handling the situation where there is not dimensional identity, in addition to the previously mentioned approaches, is to tailor a variable-oriented method to take into account group differences in model parameters. This meets the person-oriented requirement of individualizing the relationships (although normally not the requirement of taking patterns of operating factors into account). For that purpose, extensions of structural equations modeling (SEM; Bentler, 1985; Jöreskog & Sörbom, 1993; Pugesek, Tomer, & von Eye, 2003) can be a natural choice.

SEM is a broadly applicable statistical method that allows one to combine features of regression analysis and factor analysis. McArdle and Bell (2000) describe SEM as a method that provides the mathematical and statistical tools for the specification and testing of theoretical propositions. The first proposition concerns the *measurement model*, which specifies which *manifest variable* (*observed*) loads on which *latent variable* (*factor*).

Measurement models are needed to establish the loading structure of variables, both on the dependent and on the independent variables sides. If a variable fails to load on its factor, that is, if a variable shows low or nonsignificant

loadings, then researchers tend to eliminate this variable. Often, one attempts to specify measurement models such that each manifest variable loads on only one latent variable. Unless an orthogonal factor structure is hypothesized, factors are typically allowed to correlate. Second- and higher-order factors can be considered.

If one includes a regression component in the model, that is, if one links the measurement model for the independent variables with the measurement model for the dependent variables (or if one includes regression hypotheses for the factors on the dependent side of the model), then one extends measurement models into *structural models*. That is, the structural model part is the one that contains regression hypotheses in which factors are regressed onto each other.

A large number of variations of models has been proposed in the domain of SEM. For example, one can test models with only manifest variables (these are the well-known *path models*); one can test models with no variables or factors regarded as independent; one can test *longitudinal models* (e.g., von Eye, Spiel, & Wagner, 2003); one can test group-comparative models (*multigroup models*); and, recently, it has been shown that SEM can be the platform for building hierarchical linear models (for an overview, see Bauer, 2003).

Although SEM was designed with variable-oriented applications in mind, this methodological approach can be applied for some types of person-oriented analysis. From the perspective of person-oriented data analysis, multigroup models and random coefficient models are most interesting. Using such methods, the models become more individualized or person-oriented in that they take into account that the studied population is not homogeneous in the model that describes it. By such methods the issue of dimensional identity can be studied. To identify exactly where in the model groups differ, multigroup models are often performed by estimating a hierarchy of models. This hierarchy contains four hierarchically related sets of models:

1. The strictest models posit that factor loadings, factor covariances, and the regression coefficients in the structural part of the model, as well as the properties of residuals, are identical across groups. Specific groups make their own contribution to the overall goodness-of-fit χ^2 . It is conceivable that a model describes a number of groups well, but one group shows significant deviations.
2. If the strictest model fails to fit (which is likely to be the case), one can allow residuals to vary across groups while positing that all other parameters are equal across groups.
3. At the third hierarchical level, one can allow factor loadings or factor covariances to vary across groups in addition to the residuals, while the remaining parameters are posited to be invariant across groups. Often, researchers allow all estimated parameters to vary across groups. The only constraint that remains is that the same parameters are estimated in each group. Here again, groups may respond differently to this set of relaxed hypotheses.
4. If the attempts at the third level of the hierarchy fail, that is, do not lead to models that describe the data satisfactorily, one can introduce group-specific model modifications. One can, for example, allow that a selection of residual covariances be estimated for one group but not for others.

Multigroup models can be specified for practically any model in SEM. This includes models with means and longitudinal models. This option is of great importance for person-oriented research because it allows one to specify precisely where in the variable or dependency structure groups differ. For example, groups can differ in the magnitude of factor loadings. In extreme cases, factor loadings can differ to the extent that a manifest variable does load on a particular factor in one group but not the other. Structural regression coefficients can differ also. It is conceivable that a factor on the dependent variable side is predictable from a particular factor on the independent variable side in one group but not the other.

Data Example

The following data example stems from a study published by Ohannessian, Lerner, Lerner, and von Eye (1994). The authors studied perception of family functioning in families with adolescent children. Family functioning was measured as perceived family adjustment (Spanier, 1976), family adaptability (Olson, Portner, & Lavee, 1985), and family cohesion (Olson et al., 1985). In each of the 74 families, both parents and the male or the female adolescent responded to the questionnaires. One score each was created from the instruments for perceived family adjustment, cohesion, and adaptability. The instruments were administered repeatedly as part of a larger adolescent transition study (Lerner, Lerner, & von Eye, 1988). Here, we use the data from the fall and spring of the adolescents' 2nd year in middle school.

We approach these data with two questions. First, we ask whether family functioning is viewed differently in families with boys than in families with girls. Second, we ask whether the comparison of families with girls and families

with boys results in the same conclusions at both points in time. To answer these questions, we perform one two-group analysis for each data set. Because of the small number of variables, we perform the analyses at the level of manifest variables.

More specifically, the first question is answered by comparing the correlation matrices for families with girls to the correlation matrices for families with boys. The correlation matrices for the first observation point appear in Table 21.4. These correlations may be unstable, considering the small sample size. Replication studies may have to show whether the results presented here and in previous studies need to be reformulated.

The information in Table 21.4 is structured as follows. Two correlation matrices are given. The correlations above the diagonal are for families with girls. The correlations below the diagonal are for families with boys. As mentioned, the first block contains the correlations for family adjustment, the second contains the correlations for family cohesion, and the third contains the correlations for family adaptability. The first correlation in block 1 is equal to 1. It describes the correlation of the adolescents' ratings with themselves. The second correlation relates the adolescents' ratings to the mothers' ratings, and the third correlation relates the adolescents' ratings to the fathers' ratings. For example, the correlation of 0.09 in the first line relates the girls' ratings of family adjustment to their mother's ratings. The corresponding correlation in the boys' sample is 0.01.

The next series of three correlations relates the family adjustment ratings to the family cohesion ratings; following that, the series of three correlations relates the family adjustment ratings to the family adaptability ratings. This scheme is followed accordingly in the second and third blocks of the table. In each block, the first line presents correlations with adolescents' ratings, the second line pres-

ents correlations with mothers' ratings, and the third line presents correlations with fathers' ratings.

Each of these triangular correlation (or covariance) matrices can be approached from a number of perspectives. For example, one can apply methods from *multitrait-multimethod* analysis (Campbell & Fiske, 1959) and ask questions concerning the convergent and discriminant validity of a set of tests that vary in the way they measure phenomena. In the present example, the three respondents in each family would create this variation. Estimates could then be derived concerning the effect of traits and methods on the observed scores (for examples, see Kline, 2004). For present purposes, however, we compare the correlation pattern found for families with girls to the pattern found for families with boys.

Let the correlation matrix of the rating variables be labeled M . The correlation matrix of the families with girls is M_g , and the correlation matrix of the families with boys is M_b . Now, if we propose that the structures of the reported perceptions of adolescent children and their parents are identical, we posit that $M_g = M_b$. The proper null hypothesis for this proposition is $M = M_g = M_b$, where M indicates the population correlation matrix that, under the null hypothesis, both M_g and M_b were drawn from. The residuals for this two-group model are $M - M_b$ and $M - M_g$.

According to the hierarchical steps listed earlier, the strictest model is the one that proposes that all estimated parameters as well as the residuals are identical. Specifically, this model proposes that $M = M_g = M_b$ and that $M - M_b = M - M_g$. This model poorly represents the present data. We obtain a goodness-of-fit (GFI) score of 0.88 for the girl sample, the overall χ^2 is 65.93 ($df = 45$; $p = .023$), and the overall root mean square error of approximation (RMSEA) is 0.31. None of these values is in support of the strict model. In particular, the RMSEA score is far from the desired 0.05. In favor of the model is only the overall GFI = 0.92. Still, there is ample reason to reject this model.

To see which modifications are necessary to obtain a satisfactory model fit, we retracted the *invariant* option for four residuals, and we relaxed the invariant option also for four correlations, all in the boys group. Specifically, we freed the following four correlations: son-father correlation of adjustment ratings, son-father correlation of family adjustment and adaptability ratings, the correlation of fathers' perceptions of adaptability and cohesion ratings, and the correlation of mothers' perceptions of cohesion and adjustment. This model contains elements of hierarchical levels 2, 3, and 4. It describes the data very well. We obtain a GFI for girls of 0.96. The overall χ^2 is 29.33 ($df = 37$; $p = .81$). The overall RMSEA is 0.067 (indicating an

acceptable fit), and the overall GFI is 0.95. The improvement from the strictest to this more relaxed model is significant ($\chi^2 = 36.60$; or $df = 8$; $p < .01$). We thus retain the modified model.

This result can be interpreted as follows. In general, at Time 1, the degree of similarity of adolescents' and their parents' rating of family functioning is no higher than moderate. In addition, there are clear gender differences in the following four structural elements:

1. The father-son correlation of perceptions of family adjustment is lower than the father-daughter correlation.
2. The correlation between the girls' perceptions of family adjustment and adaptability is higher than for the boys' perceptions.
3. In the girls' group, the correlation between fathers' perceptions of adaptability and cohesion is lower than in the boys group.
4. The correlation between mothers' perceptions of cohesion and adjustment is lower in the girls' than in the boys' families.

Interestingly, and this result was reported already by Ohannessian et al. (1994), it also seems that the correlations in the boys' families are, on average, lower than in the girls' families. This result makes one wonder whether the instruments used to rate family functioning are equally valid for girls and boys in this age group of 11- to 12-year-olds.

Both sets of results, the structural differences and the differences in the magnitude of the correlations, are of importance from the perspective of person-oriented analysis. It is not just the case that mean ratings differ (Ohannessian et al., 1994). It is also the case that the structure of rating elements differs across boy and girl families. One thus can doubt that dimensional identity exists. That is, one can doubt that the ratings in the two family groups have the same dimensional structure.

If indeed there is no correspondence between the dimensional structures of the ratings, mean comparisons are hardly valid. We thus have to conclude that the earlier results reported by Ohannessian et al. (1994) for this age bracket have to be interpreted with caution. The instruments used to assess the parental and adolescent perceptions of family functioning may be differentially valid for boy and girl families. Specifically, it seems that whereas the correlations of the girls' ratings and the correlations of the parental ratings are about equal in magnitude, the corresponding correlations for boy families are lower. We thus suspect that boys in particular harbor different concepts of

family functioning than girls and parents. Considering the implications of discord (see later discussion), this result needs further study because discord can be observed at the level of magnitude of ratings but also at the structural level.

It may very well be that this lack of structural identity has a developmental aspect to it in that boys may grow to use the same structure of family functioning as girls and parents. If this is the case, the comparison of the correlation matrices at the second point in time will show fewer discrepancies. Table 21.5 displays the same correlation matrices as Table 21.4, based on the data from Time 2.

In comparison with the correlations at Time 1 (Table 21.4), the correlations at Time 2 are generally higher in both groups. In addition, they are of about equal magnitude in both groups. This is most important from a differential validity perspective. When the correlations are equal in magnitude, one can assume that the validity of the instruments used in this study is, at Time 2, no longer gender-specific.

We now ask whether the correlation matrices for girl families are, at Time 2, also structurally more similar to the correlation matrices for boy families. As in the analysis of the correlations in Table 21.4, we begin with the strict model that requires all parameters to be equal. That is, we begin with the model that hypothesizes that $M_g = M_b$ and $M - M_g = M - M_b$. This model fits poorly. We obtain GFI = 0.86 for girls, an overall $\chi^2 = 116.33$ ($df = 45$; $p < .01$), an overall RMSEA = 0.13, and overall GFI = 0.89. These results are about as bad as for the correlations in Table 21.4. However, only half the number of modifications was needed to obtain a model that describes the data well. Only one correlation in the boy families needed to be allowed to differ from the corresponding correlation in the girl families (the correlation between mothers' and their boys' perceptions of family cohesion), and one residual

TABLE 21.5 Correlation Matrices for Family Functioning Variables at Time 2

.35	.03	.11	.32	.08	.13	.37	.52	1

covariance in the boys' group and two in the girls' group needed to be freed. With these modifications, we arrived at a well-fitting model. We obtained $GFI = 0.95$ for girls, the overall $\chi^2 = 45.58$ ($df = 41$; $p = .29$), the overall $RMSEA = 0.015$ (indicating exact fit), and the overall $GFI = 0.93$.

From these results, we conclude that, at Time 2, the structural differences between ratings in girl families and ratings in boy families are minimal. In addition, they are reduced as compared to the first observation point. Regardless of whether this change in structural comparability reflects development, differential responses to repeated administration of the same instruments, or both, these small differences do not prevent one to directly compare the correlations and means. The mean comparisons performed by Ohannessian et al. (1994; Ohannessian, Lerner, Lerner, & von Eye, 2000) can thus be defended. Ohannessian et al. had reported that mean differences exist. Both boys and girls reported lower levels of family cohesion than did their parents. Girls also perceived lower levels of family adjustment than did both parents. Discrepancies in perceptions of family functioning were also related to adolescents' reported increased levels of depression and anxiety, in particular for girls.

In general, we see that level of ratings and structure of ratings are independent of each other. Even if the structure is perceived in the same way, there can be mean differences. If construct validity is established using correlation patterns, then there is a hierarchy in analytic procedures. If there are substantial differences between correlation or covariance structures, then mean differences may be hard to interpret, because differences in covariance structures may indicate different interpretations of items in questionnaires or tests. Therefore, structural equivalence or identity needs to be established before hypotheses concerning mean comparisons are meaningfully entertained.

From the perspective of person-oriented research, we note that groups of individuals can differ in any parameter. These include means, standard deviations, higher-order moments, covariances, covariance structures, factorial structures, factor loadings, and factor loading patterns. Each of these needs to be tested for equivalence across groups before dimensional identity can be considered fully established.

SOME COMPUTER PROGRAMS FOR CARRYING OUT PERSON-ORIENTED ANALYSES

Many of the analyses discussed in this chapter can be accomplished with a sophisticated use of the standard statis-

tical packages such as SPSS and SAS. The most extensive package for cluster analysis is the CLUSTAN package (Wishart, 1987). All LICUR-type analyses, as well as ISOA and TYFO, can be performed using the SLEIPNER package, which was developed especially for person-oriented analyses (Bergman & El-Khoury, 1998; Bergman et al., 2003). SLEIPNER also contains modules for the exact analysis of single cells in contingency tables. Packages especially designed for CFA have been developed by von Eye (2001) and Krauth (1993). Waller and Meehl (1998) indicate programs for performing taxometric analyses, and Collins and Wugalter (1992) have created a program for carrying out LTA.

DISCUSSION

In this concluding section we discuss person-oriented approach from a number of different perspectives and point to future paths.

The Need for Person-Oriented Strategies in Developmental Psychopathology

By now, the reader is familiar with a variety of person-oriented strategies that can be used to carry out research in the field of developmental psychopathology. What they have in common is that the focus of analysis is not on the variable, studied across individuals, but rather on the individual as an integrated organism, as captured by the available information. In an interindividual context, this usually means that, in one way or another, information is searched for categories of subjects where each category is homogeneous in a number of variables considered simultaneously and across time.

It has been said repeatedly that we need to move away from studying associations between variables and instead study mechanisms if we want to increase our understanding of developmental phenomena (see, e.g., Magnusson, 1988; Rutter, 2004). It is our belief that this is especially true in the field of developmental psychopathology. We have learned a great deal about basic relationships by studying simple developmental associations, but to further advance our knowledge about the processes and to formulate theories that explain them we need to use approaches that are *theoretically informative*. By this we mean that the results are interpretable in such a way that estimated parameter values, result structures, and so on have an affinity to the theoretical concepts believed to hold (see Richters, 1997).

For instance, if it is believed that continuous functional interactions operate and crystallize in typical syndromes of psychopathology, a methodological approach should be used that reflects this. We believe a person-oriented strategy, appropriately carried out, in many situations can produce theoretically informative results for understanding developmental mechanisms.

A person-oriented research strategy has been criticized from mainly two perspectives. The first line of criticism has its starting point in an acceptance of the variable-oriented research paradigm and a belief that the standard methods used in this paradigm are (almost always) valid and useful and provide a rather complete toolbox. To give just one example: It is believed by some that a structural equation approach, studying linear relations over time, would, if competently executed on good data, give in-depth information about the process in which psychopathology is formed. Different models could be tested and the results would provide valuable information for advancing theories in the field. According to this extreme variable-oriented perspective, there is no real need for other types of approaches. We believe such a rejection of person-oriented research strategies out of complacency is misplaced and dangerous. In this chapter, we have strongly argued that, from a holistic-interactionistic paradigm, it is quite problematic to carry out research on the developmental processes of psychopathology at the group level that rely on linear models and on the study of relations between pairs of variables. Then one has to make strong assumptions about the process under study, assumptions that, in many situations, are hard to defend. We do not live in a linear world; linear models are used mainly for reasons of mathematical convenience and not because they correspond to the dynamics believed to hold for the processes we are interested in (cf. Brown, 1995).

The second line of criticism against using a person-oriented research strategy focuses on problems with the methodological implementation of this approach. Thus, the criticism is not against the strategy as such but against the means of carrying it out. This type of skepticism must be taken seriously. Undoubtedly, there are difficult issues that must be handled satisfactorily to carry out a successful person-oriented analysis. In the following, a number of such issues are discussed.

Establishing the Trustworthiness of the Results from a Classification Analysis

In this section, we discuss how to establish the trustworthiness of a classification obtained in a developmental set-

ting. We do this from the starting point that a cluster analysis-based method has been used to produce the basic classifications, but much of the reasoning also holds when other types of classification methods have been used. The presentation is largely a summary of work by Bergman et al. (2003). Admittedly, this overview is restricted to the present authors' perspectives; for a broader overview, the reader should refer to Blashfield (1980), El-Khoury (2001), Meehl (1992), and Milligan (1980, 1981, 1996).

Let us start with the examination of the results of a single cluster analysis, which is the basic building block in most types of developmental classifications. A number of procedures can be carried out to establish the trustworthiness of this cluster solution:

- The homogeneity of the clusters is studied (i.e., to what extent the cluster means in the variables represent the individual profiles belonging to each cluster). Two ways of studying the homogeneity are:
 - a. To compute the averaged squared Euclidean distances between all members in a cluster. For the whole sample and standardized variables (i.e., the one-cluster solution), this coefficient is 2.00. A value below 1.00 for a cluster is sometimes regarded as a minimum requirement and a value below 0.50 is often regarded as desirable.
 - b. To compute the percentage of the total error sum of squares that is explained by the cluster solution (EESS). Bergman (1998) suggested that a value of at least 67% is often desirable. Of course, there are other indices that measure the "quality" of a cluster solution or a whole classification tree. For instance, the point biserial correlation and the gamma coefficient could be used for that purpose (see the sources mentioned earlier for details).
- Whether a model of no relationships can be rejected is investigated. It can be studied if the cluster solution shows evidence of being a "real structure." A cluster analysis will find some structure even in random data, and we may want to dismiss the possibility that the reported cluster solution is compatible with such a trivial null hypothesis. For this purpose, a significance test procedure of EESS (or some other measure of cluster homogeneity) can be used that is based on data simulation. Artificial data are produced that are of the same type as the real data but where all relationships between the variables have been wiped out. It is then tested if the EESS is higher for the real data set than for the artificial data sets. This testing is, in principle, slightly similar to

the significance testing of a correlation coefficient; it is described in Bergman et al. (2003).

- The stability of a cluster solution can be studied when the method for cluster analysis and the sample are varied. With regard to sample size, as can be expected, the detailed results from a cluster analysis are not very stable to sampling variation if the sample is small (Milligan, 1980). Therefore, a split-half analysis demands a certain initial sample size, say 400 to 500 subjects. For smaller samples, one might have to accept a less satisfactory sampling variation study and, for instance, rerun the results on a random three-fourths of the original sample. To also study the effects on the results of method variation, another method can be chosen. For instance, beta-flexible cluster analysis could be used with the parameter set to, say, -0.15 . The results of the original cluster analysis are then compared to the results obtained after the method variation was implemented. In principle, two types of comparisons can be made: The centroids of the two cluster solutions are compared, using multidimensional scaling or some other method to see if the same typical profiles are obtained or if the focus is on the quality of the assignment of subjects to clusters, for instance, the Rand index is used to compare the classifications (see El-Khoury, 2001, for overviews of different coefficients for comparing cluster solutions). It is also possible to use the classification rules generated by the use of a cluster analysis of one sample to classify another equivalent sample and then compare these results to those obtained by directly cluster analyzing the equivalent sample.
- We can obtain some idea of the power of the cluster solution to account for the linear correlations between the variables that constitute the value profile that was studied in the cluster analysis. Lazarsfeld (Lazarsfeld & Henry, 1968) has suggested that one criterion for a “real” latent class is that, within a class, all the correlations between the variables should vanish (local independence). Following his line of reasoning, one can study if the correlations among the variables in the profile are strongly reduced or disappear when the correlation analysis is done *within* each cluster. This would indicate that the cluster solution can “explain” the correlations between the variables.
- Differences between the clusters can be studied in validation variables. If the reported classification structure is informative, we should find differences between the clusters in the theoretically expected direction for important validation variables.

If the longitudinal classification is done in one step, then these procedures are directly applicable. If the classification is first done separately at each point in time and then the classifications are linked, as in LICUR, then the establishment of the trustworthiness of the final classification structure is more complex. A first step could be that these procedures are applied to each cross-sectional classification separately. The whole LICUR sequence of analyses could also be rerun after varying the sample and method.

However helpful these procedures are for establishing the trustworthiness of a classification, they do not directly answer the question of whether, in some sense, a true or “natural” classification has been obtained. This difficult issue was briefly discussed in a preceding section when Meehl’s procedures for taxometric analysis were introduced. Our own position is rather pragmatic. If a classification has been shown to be trustworthy and if it leads to theoretically meaningful predictions, then it is useful and deserves to be taken seriously. As Meehl (1992) pointed out, it is difficult—and may not even be necessary—to define what is a natural cluster or taxon, and we might have to be satisfied with some provisional definition.

Combining a Variable-Oriented and a Person-Oriented Approach

Many experienced researchers would probably agree with us that the choice between a variable-oriented and a person-oriented research strategy cannot be made without reference to the specific problem under study, as discussed in various places in this chapter. We would add that, in some situations, it might be useful to combine these two research strategies in the same study for a number of reasons:

- In this way, a binocular view may be obtained. The results and theories related to a variable-oriented and a person-oriented approach often refer to quite different perspectives on reality. However, in some cases, they can relate to the same scientific problem, and if the results of these two different methodological approaches then support each other, it increases the confidence that the findings are not method-bound. For instance, the claim for having found an important externalizing personality dimension obtains additional general value if it is found not only by a factor analysis, showing high loadings in the relevant variables, but if a personality type is also found, characterized by a profile that is high (or low) in all the relevant variables.
- As mentioned earlier, an initial variable-oriented study of the relationships in data can be of use for identifying relevant variables and obtaining a preliminary picture of

how the variables to be studied are related. This information can be helpful in identifying the relevant variable profile to be studied in a person-oriented analysis.

- Interactions and nonlinearities can sometimes to a certain extent be handled by a variable-oriented approach, for instance, by applying nonlinear regression analysis—if one knows beforehand what interactions to specify. If one does not know that, then one might carry out a preliminary person-oriented pattern analysis to obtain information about likely interactions in the data set and use that information to define the interaction terms.

Classes and Continua

Physics advanced when the categorical approach of the scholastics was replaced with a dimensional approach, based on measurement and mathematics. Making the jump to psychiatry and, especially, to psychology, the use of objective measurement techniques and of statistics, based on the analysis of variables, has advanced these sciences beyond what would have been possible if research had relied on a categorical, typological approach (see Ekman, 1951, for a critique of the old typological approaches). However, these facts should not be overinterpreted, as pointed out by, for instance, Bergman (1998) and Meehl (1992). In defense of the judicious use of a modern classificatory approach, the following can be said:

- In contrast to what is the case for the old typological approaches, the input in a modern typological analysis is usually the same dimensional data that are used for standard analyses. This means that the classification can be done objectively and that the results can be checked against those obtained using other methods.
- All data analysis implies some sort of simplification or summary; some “model” is always produced to represent the data. Therefore, a typological representation should not be compared to the original data set and found deficient if it does not cover all aspects of these data. Rather, the comparison should be between the typological representation and an alternative standard model of the data, for instance, a regression model or a structural equation model, and with regard to which representation best reflects the essential characteristics of the data.
- A modern classificatory approach should, in many situations, be regarded as a method for obtaining information about the effects on the studied system of higher-order interactions and nonlinear relationships, information that cannot be obtained by standard variable-oriented methods. This does not mean that the classificatory ap-

proach should be regarded as the end point. Rather, in our opinion, in the future it will become possible in many situations to apply nonlinear dynamic systems models that will be superior in certain respects: superior in that they can provide a powerful mathematical model of the process of psychopathology development that takes continuous interactions into account and that provides a model of the change process—in contrast to most statistical models that primarily provide a static model of data referring to discrete time points (Bergman, 2002).

We believe we can learn from the history of science with regard to the categorical or classificatory approach versus the variable-oriented dimensional approach that the severe limitations of the early types of the first approach naturally led to a major shift in focus to the other type of approach. Now, as our knowledge base has advanced and we have become more interested in sophisticated questions involving interactions and so on, the limitations of standard variable-oriented approaches become obvious. For certain classes of problems, it is then natural to move on to a modern typological approach. No doubt, more advanced dimensional and typological approaches will emerge, and both classes of approaches will be needed.

It must be pointed out that when we reviewed classificatory approaches we focused on methods that provide mutually exclusive clusters. In, for instance, latent class analysis, the allocation of subjects to classes is probabilistic and there also are other types of methods that allow for overlapping clusters: A subject can be regarded as belonging to more than one cluster. However, allowing for overlap can give complex results that are difficult to interpret. If a weight is given for each subject, indicating his or her degree of closeness to each cluster, then we are, in a way, back at a variable-oriented representation but of a rather strange kind, with a multidimensional density, called a cluster, being treated as a unidimensional variable.

Observation versus Theory Testing

Most researchers would probably agree that in the initial stages of a new field, careful open-minded observation is of crucial importance. Help from theories in what to look for is, of course, important but, as formulated by Bergman and Magnusson (1997, p. 315), “Theories prematurely transformed into statistical models of data can become blinkers. If the model window opens at the wrong place, the interesting things may be missed.” This is by no means a new point. It has been made many times before by, for

instance, Cronbach (1975), Greenwald, Pratkanis, Lieppe, and Baumgardner (1986), and Magnusson (1992). We would argue that one is usually at this initial stage when applying a person-oriented approach to understand a developmental process in the psychopathology field. Therefore, the use of methods that are descriptively oriented—in the sense that they do not attempt to construct a comprehensive model of the data—should be regarded as natural in many cases and often more appropriate than premature model-based approaches at this stage. Besides, also with so-called descriptive classification approaches, procedures exist for testing theoretical predictions of, for instance, developmental streams.

In a person-oriented framework, the following sequence of analyses often seems to be natural: (1) preliminary variable-based analyses to identify operating factors, create measurement models, and aid in the formulation of relevant patterns; (2) predominantly descriptive pattern-based analyses, including testing that the results are consistent with theoretical expectations; and (3) predominantly model-based pattern analyses for formulating and testing models of person-oriented theories.

Prediction and the Person-Oriented Approach

We believe that it is dangerous and misleading to set up predictive power as the main criterion for a successful theory or method. This point was made by Magnusson (1985) and Bergman and Magnusson (1997). They discussed the issue in relation to the empirical examples they gave in their article that dealt with the study of patterns of adjustment problems from childhood to adulthood and pointed out that the following very simple argument is often used against a pattern approach: The prediction of an adult maladjustment variable can be (almost) maximized by using a linear model, and the prediction is usually not improved by considering more elaborated models. Therefore, the connection of typical patterns of childhood problems to typical patterns of adult problems is not likely to lead to more precise predictions of an outcome variable, and until that has been shown, it is to be regarded an unnecessarily complex approach.

To this argument it can be added that because linear models are optimized to maximize prediction, they are likely to do better than other approaches that are not optimized for this purpose. However, this is true only with modification. The success of the prediction can be measured in different ways, and usually the square of the correlation between the actual value and the predicted value is used for that purpose. This is a definition that largely

has arisen out of mathematical convenience, and it happens to be the one that the linear prediction equation is built to maximize.

The relevancy of the prediction argument, of course, stands and falls with the assumption that prediction is the goal. As underlined by Magnusson (1985), this is a simplistic perspective. To be able to predict a phenomenon is neither sufficient nor necessary for understanding it. Meteorologists understand fairly well what factors regulate the weather and its dynamics, and yet, long-term prediction of the weather on a specific day is inherently unreliable due to the principle of infinite sensitivity to the initial conditions leading eventually to chaos. In spite of this, few would, for that reason, call meteorology a primitive science. We can also show that it is possible to have powerful relations across time for patterns and yet to have all pairwise correlations be zero (see, e.g., Bergman, 1988a, 1998). Are these interactions irrelevant just because no *linear* prediction can be made? Bergman and Magnusson (1997, p. 316) summed up their arguments against prediction as the main goal in the following way: “We have pointed in this article to typical patterns of adjustment problems in childhood that are connected to typical patterns of problems in adulthood. The value of such results cannot be measured by some prediction coefficient pertaining to a linear model alien to a pattern approach.”

The Boundaries of Development

It is an interesting thought that, as much as we want to study what happens through development and that these findings can tell us important things about the process of developmental psychopathology, we can also learn about this process by finding out what does *not* happen in development. Together, these two complementary perspectives teach us about the boundaries of development. The issue was touched on in the empirical example about studying white spots given in an earlier section.

Of course, this idea is by no means new. For instance, Lewin (1933, p. 598) discussed boundary conditions in terms of “region of freedom of movement,” and Valsiner (1984) pointed out that a person’s observed behavioral variability is only a fraction of its possible range of variability. An early advocate of the importance of this perspective was Lienert (Krauth & Lienert, 1982), who, within the framework of CFA, introduced the term antitype for an observed value combination that occurred more rarely than one should expect by chance. Bergman and Magnusson (1997, p. 309) introduced the term white spots for patterns that rarely occurred (but were not necessarily

antitypes). These white spots could be searched for using different methods. Some ways of doing this cross-sectionally are presented in the methods section (searching for antitypes, identification of a residue, etc.). It can also be made developmentally, looking for pathways of pattern development that for some reason are closed, using, for instance, the LICUR procedure.

This reasoning may be of special relevance for the study of psychopathology as it is at the boundaries of what can occur when “normal” development has gone off track.

CONCLUSION AND FUTURE PERSPECTIVE

What is psychopathology from a person-oriented perspective? Does this perspective lead to a radically different view on the important phenomena collected under that heading? We would argue that this may not be the case as the theoretical framework that we have put forward in this chapter is rather akin to the theoretical thinking of most researchers who study developmental psychopathology. (It is another matter that the approach put forward here is at variance with most common *methodological* approaches that are used in the developmental psychopathology field, as these are variable-oriented and tend not to correspond to the interactionistic notions about the psychopathology process that most researchers have.) In this context and from the vantage point of the person-oriented perspective, Bergman and Magnusson (1997) made the following observations.

Psychopathology is a set of states of the dynamic systems describing the development of psychiatric health, states that usually are not common in the general population and that are in certain ways maladaptive. Many such states tend to be “recognized” by the individual’s dynamic system as being nonoptimal. Hence, they often should be expected to be transient and not stable. We therefore often expect fluctuating symptomatology through development, even through short time spans, and these changes merit investigation. They should be contrasted to more stable psychopathological states, characterized by symptoms that often occur in typical syndromes of maladaptive behavior, feelings, and so on. Such states, indicating a specific typical pattern of psychopathology that exhibits individual stability across time, must have powerful factors that keep throwing the individuals off track in such a consistent way. It is a surmise that there are probably only a very limited number of constellations of operating factors that can accomplish this for a certain syndrome, and only a very limited number of syndromes that show long-term stability. To

identify these, as we discussed, studying both typical patterns (e.g., using classification analysis, analyzing dense points) and white spots seems to be a promising avenue of research in the field of developmental psychopathology. The importance of studying different types of variables in psychopathology, as advocated by Cicchetti (1993), supports this focus on patterns of operating factors.

In spite of possible technical imperfections and so on, the person-oriented strategy has a reasonable correspondence to many researchers’ theoretical conceptualizations of how the phenomena operate. We claim that, in many situations, this is not the case with standard variable-oriented methods, and that this correspondence—the match between problem and method—should be the single most decisive factor when selecting a methodological approach (Magnusson, Bergman, Rudinger, & Törestad, 1991). Richters (1997) has eloquently argued for the existence of what he calls the developmentalist’s dilemma, by which he means the contrast between the open systems theoretical concepts in developmental psychopathology and the closed systems approach usually applied, taken from mainstream developmental psychology. Although he means something more and different from the mere application of a person-oriented research strategy, we claim that this approach to a certain extent answers his call for a research paradigm that is more aligned to the complexity of the developmental phenomena we are interested in.

Already today there exists a large toolbox of useful person-oriented methods to carry out research on developmental psychopathology, both model-based and more exploratory. The infusion of ideas, models, and technical solutions from the field of nonlinear dynamics will also give a powerful impetus to a more sophisticated study of psychopathological processes. In doing this, it is possible that we will rediscover the primary importance of studying the single individual, not only as case studies in clinical work but also in rigorous research aiming at revealing mechanisms involved in the emergence of psychopathological conditions. In fact, we feel uneasy about the present overreliance on the study of interindividual differences as the road to understanding influences that operate at the level of the single individual. As we discussed earlier, for this to be a valid approach, you have to make a number of assumptions. A challenge for the next generation of methodologists will be to find new ways of combining the study of several single individuals with a sound strategy for how to generalize the findings.

An aspect of the person-oriented approach that partly overlaps what has been presented in this chapter has to do with the different perspective taken with regard to making

inferences to individuals from group data, as compared to what is typically the case in the variable-oriented approach. The latter approach proceeds under the assumption that samples are typically drawn from one large parent population. This population is typically normally distributed. Samples are considered representatives of the population, and sample statistics are sufficient, efficient, and unbiased estimates of population parameters. In contrast, the assumptions that need to be made for person-oriented research include multiple populations, nonnormal distributions, and often nonlinear variable relationships (Bergman, 1998). Research may qualify as at least partly person-oriented if researchers focus on the establishment and comparison of homogeneous groups of individuals that differ in function and development even if no explicit study is made of patterns of operating characteristics. These groups are either defined *a priori*, for example, the women in violent relationships versus women in nonviolent relationships, or need to be found in larger samples, for example, the trajectories of recovery in alcoholics. In this context, in a discussion with Molenaar (2004), von Eye (2004) noted an important implication of the wider adoption of person-oriented scholarship. It implies an increase in the number of models at the data level that are needed for valid description of human functioning and development. If one model is insufficient to describe the whole population, more than one model is needed. Some of these models will differ fundamentally, for instance, in the number of factors needed to describe a phenomenon or in the structural elements of a path model. The means of statistics can be used to decide whether a different model needs to be specified for a subgroup of individuals, or whether a model needs to be updated because of the developments in a population over the course of historical time.

With regard to future methodological developments, von Eye and Schuster (2000) identified six general trends for the future:

1. There will be an increase in the number of available statistical methods, as new statistical methods are being developed at a very rapid pace.
2. Substantive thinking triggers the development of new methods of data analysis.
3. Statistical methods become increasingly flexible.
4. Computers do the thinking. Expert systems and built-in checks of whether the conditions for proper application of statistical methods are fulfilled will make the selection of methods of analysis easier, if not foolproof.
5. There will be new research paradigms, such as the person-oriented approach. These new paradigms will lead to statements that are more valid and describe a larger portion of the population. However, these statements will also be more complex, and they require more effort.
6. Statistical methods will be custom-tailored to substantive questions.

These six trends indicate that the emergence and development of new paradigms and research questions in the context of person-oriented scholarship has a transactional, reciprocal relationship with ongoing efforts to develop more useful methods of data analysis. Thus, there will be cross-fertilization to the benefit of both the fields of statistics and substantive research. The person orientation as a research paradigm is also constantly being developed itself. For instance, von Eye and Bogat (in press) discussed the relationship of person-oriented scholarship to differential psychology. The authors note that differential psychology is based on the assumption that all individuals can be placed on different locations of the same scales. In contrast, person-oriented concepts go a step further in that the idea that the same scales are applicable to everybody is challenged.

Perhaps the most important vehicle for promoting the person-oriented approach is a good training of young researchers in it. This training must comprise three parts: (1) introduction to the theory behind the approach and the motivation for it, (2) presentation of selected methods and training in how to use them, and (3) the provision of good empirical examples of the use of the person-oriented approach. Today it is a problem that few universities have methodologists who are experts in this approach. While waiting for this situation to change, it is an important duty for those of us who have this expertise to arrange such courses, preferably as internationally open workshops. Then we cannot underline enough the importance of (1) when such a course is planned. Often, students want to go straight to learning and applying an exciting new methodological tool, but if the theory that motivates its use is not understood, the chances are slim that good research will come out of it.

FUTURE DIRECTIONS: IMPLICATIONS FOR CLINICAL RESEARCH	923
CONCLUSION	925
REFERENCES	926

Decades ago, Lewin (1931) criticized psychology for its overreliance on methodologies that were originally designed for studying closed, physical systems. These methods, he warned, were inappropriate for the study of complex, developmental processes. Over 70 years later, the same criticisms continue to be raised, and with increasing urgency. Specifically, leading theorists (Cicchetti & Cohen, 1995b; Ford & Lerner, 1992; Hinde, 1992; Kagan, 1992; Keating, 1990; Overton & Horowitz, 1991; Richters, 1997) suggest that there is a fundamental incompatibility between developmentalists' organismic, open systems models and the mechanistic research methods with which these models are tested.

An earlier, less detailed version of this chapter appeared in *Development and Psychopathology*, 15 (2003). We gratefully acknowledge the financial support of Grant 1 R21 MH 67357 from the National Institute of Mental Health (to D. Pepler and I. Granic) as well as Grant 410-2003-1335 from the Social Sciences and Humanities Research Council of Canada (to the first author).

Developmental psychopathologists have been particularly concerned with their inherited mechanistic paradigm. Many of them have developed heuristically rich, complex models based on open systems concepts, but little headway has been made in finding alternative analytic tools appropriate for testing these models—a predicament Richters dubbed “the developmentalist’s dilemma.”

In this chapter, we suggest that methods derived from dynamic systems (DS) theory may be useful for addressing this dilemma. We have three main objectives: (1) to outline key dynamic systems principles and highlight their commensurability with developmental psychopathologists' core conceptual concerns; (2) to provide a survey of research designs, methodological techniques, and measurement strategies currently being used and refined by developmental DS researchers; and (3) to elaborate on one specific DS method, state space grid analysis, and provide several empirical examples using this method. The state space grid approach (Lewis, Lamey, & Douglas, 1999) was developed as a middle road between DS methods that

are mathematically demanding (and, thus, often inaccessible or inappropriate for developmental psychopathology) and those that are purely descriptive. We have included most DS methods currently available for developmentalists. The methodological techniques and specific examples we have selected were chosen because they seemed most appropriate for addressing the types of research questions developmental psychopathologists tend to pursue. In the end, however, our main purpose is to provide a clear enough picture of various DS methods to inspire developmental psychopathologists to expand their analytic repertoire and, thus, test their systems-based models more directly.

THE DEVELOPMENTALIST'S DILEMMA

Before proceeding to discuss DS theory and its methodological bag of tricks, we briefly review the strong rationale for developing new methods for the field of developmental psychopathology (also see Cicchetti & Cohen, 1995b). Developmental psychopathologists have adopted an organismic, holistic, transactional framework for conceptualizing individual differences in normal and atypical development (e.g., Cicchetti, 1993; Cicchetti & Cohen, 1995a, 1995b; Cummings, Davies, & Campbell, 2000; Garnezy & Rutter, 1983; Sameroff, 1983, 1995; Sroufe & Rutter, 1984). These scholars often frame their models in terms of organizational principles and systems language. The systems theories that inform these models include General Systems Theory (Sameroff, 1983, 1995; von Bertalanffy, 1968), Developmental Systems Theory (Ford & Lerner, 1992), the ecological framework (Bronfenbrenner, 1979), contextualism (Dixon & Lerner, 1988), the transactional perspective (Dumas, LaFreniere, & Serketich, 1995), the organizational approach (Cicchetti & Schneider-Rosen, 1986; Erickson, Egeland, & Pianta, 1989; Garnezy, 1974; Sroufe, 1979, 1986; Sroufe & Rutter, 1984), the holistic-interactionistic view (Bergman & Magnusson, 1997), and the epigenetic view (Gottlieb, 1991, 1992). As a class of models, these approaches focus on process-level accounts of human behavior and on the context dependence and heterogeneity of developmental phenomena. They are concerned with the equi- and multifinality of development, the hierarchically embedded nature of intrapersonal (e.g., neurochemical activity, cognitive and emotional processes), interpersonal (e.g., parent-child relationships; peer networks), and higher-order social (e.g., communities, cultures) systems. They are also

fundamentally concerned with the mechanisms that underlie change and novelty (as well as stability) in normal and clinically significant trajectories.

As a result of inadequate measurement techniques, however, the complex developmental models informed by the language of systems thinking remain largely untested (Richters, 1997). For example, in the field of childhood aggression, a number of leading scholars have become concerned with highlighting the heterogeneity of aggressive youth and advocating the development of causal models that recognize the equifinality of aggression (e.g., Cicchetti & Richters, 1993; Hinshaw & Zupan, 1997; Moffitt, 1993). But it remains difficult to test these models because most of our current research methods and analytic techniques (e.g., regression analysis, t-tests, path analysis) rely on strategies that aggregate overtly similar subjects into one group or another (e.g., aggressive and nonaggressive children) to conduct group-level statistical analyses. Thus, although we may know that aggressive children show the same behavioral pattern for very different reasons (e.g., abuse, permissive parenting, marital conflict, birth of a new sibling), this variability cannot be systematically addressed because multivariate analytic strategies carry an *a priori* assumption of within-group homogeneity. This is not just a niggling statistical detail. Several leading methodologists have argued that, in most cases, these assumptions are completely unfounded and have likely led to serious misinterpretations of data (e.g., Hinshaw, 1999; Lykken, 1991; Meehl, 1978; Richters, 1997).

How did this gap between methods and models come about? Numerous critics (e.g., Hinde, 1992; Meehl, 1978; Lykken, 1991; Overton & Horowitz, 1991; Richters, 1997) have pointed to psychology's original sin for an explanation: In an effort to gain credibility and align itself with the hard sciences, psychology appropriated the methods and analytic techniques of mechanistic, nineteenth-century physical sciences. This paradigm is inappropriate for the study of self-organizing, active, reactive, interactive, and adaptive organisms (i.e., the stuff of psychology). The irony is that psychology's embrace of this mechanistic paradigm came at the same time as the physical and biological sciences were advancing a radically new one—one based on open systems concepts (Overton & Horowitz, 1991; Richters, 1997).

For some domains of psychology, adopting techniques from statistical mechanics may not be as paralyzing as it has become for developmental psychology (Thelen & Smith, 1994, 1998; Thelen & Ulrich, 1991; van Geert, 1998b, 1998c). At the heart of developmental questions,

however, is how things *change*. By what process do novel structures (e.g., formal operational thought) or skills (e.g., emotion regulation, walking, language) emerge? The pioneers of developmental science (Piaget, Vygotsky, Werner) concerned themselves with the pursuit of abstract laws or properties that govern development: the structural explanation of how development unfolds (Cicchetti, 1990; van Geert, 1998b, 1998c). As van Geert (1998b) has argued, however, change and the emergence of novelty may no longer be the focus of contemporary developmental psychology. This state of affairs can be traced to the “adoption of a statistics that was designed for different purposes, namely distinguishing populations characterized by some special feature . . . and estimating the linear association between the variance of some independent variable on the one hand and a dependent variable on the other” (p. 146). The adoption of such statistics seems to have missed the point of the original questions laid out by the founding scholars of developmental science (Thelen & Smith, 1994; van Geert, 1998b).

Developmental psychopathology, having grown in part from this tradition, inherited the same schism. But developmental psychopathology also grew from several other disciplines that were less hampered by this statistical baggage. Embryology (e.g., Kuo, 1967; Spemann, 1938) was one of these disciplines (for a review, see Cicchetti, 1990). In the pursuit of understanding normal embryological functioning, “early embryologists derived the principles of a dynamically active organism and of a hierarchically integrated system that were later used in investigations of the processes of abnormal development within the neurosciences, embryology, and experimental psychopathology” (Cicchetti, 1990, p. 4). These insights formed the basis for the organizational approach in developmental psychopathology. Another avenue of influence comes from the discipline of ethology, which views the organism as a comprehensive whole and advocates a “multidomain, multidiscipline approach to psychopathology” (p. 19), an approach that is at the heart of developmental psychopathology (see also Hinde, 1983).

Interestingly, developmental psychopathology also shares its roots with the founders of child psychoanalysis (e.g., A. Freud, Klein, Winnicott, Bowlby, Erikson) who, like Piaget and Vygotsky, formalized theories based on detailed observations of children in their natural environments (Cicchetti, 1990; Cicchetti & Cohen, 1995b). These original, individual-based, ethnographic methods, however, are rarely applied in contemporary research (but see Cicchetti & Aber, 1998, for an exception). Yet it seems clear to us that these

organismic, systems-oriented roots lend themselves well to DS principles and the methods they suggest.

As it stands now, the field of developmental psychopathology seems to be at an impasse. On the one hand, some scholars have suggested that systems approaches to studying development have provided an interesting metaphor, but offer little more (Cox & Paley, 1997; Reis, Collins, & Bersheid, 2000; Vetere & Gale, 1987). Thus, one option is to give up the search for the grail, abandon this well-intentioned enterprise, and build simpler, more linear models that can be tested with established statistical rigor. Another option is offered by Richters (1997, p. 226): “Resolving the developmentalist’s dilemma will require more than a recognition of the inadequacies of the existing paradigm. It will require intensive efforts to develop indigenous research strategies, methods, and standards with fidelity to the complexity of developmental phenomena.” At the close of his essay, Richters offered some general instructions for how this new generation of studies should proceed:

1. There should be intense focus placed on understanding *individuals* and the causal structures that underpin specific individuals’ development, with particular attention to “well-characterized exemplars” (i.e., nonextreme) cases.
2. No single method should be held as superior or inferior (e.g., case-based, variable-based, cross-sectional, longitudinal, historical, ethnographic); instead, methodological pluralism should be encouraged and may vary in degree depending on the phenomena investigated.
3. “Ritualized” hypothesis-testing should be generally abandoned for more exploratory, creative approaches that emphasize the discovery process.
4. A narrow focus on “explained variance” and prediction should take a secondary role to explanatory power.

These directions provide the springboard from which to consider the potential contributions that DS methods can make to addressing systems-inspired models.

PRINCIPLES OF DYNAMIC SYSTEMS

Developmental psychopathologists will be familiar with most of the concepts in DS theory because of their longstanding familiarity with systems concepts in general. Nevertheless, for the sake of clarity and precision, we believe it is important to delineate this framework from

the systems approaches mentioned previously (Lewis & Granic, 2000).

Formally, a *dynamical system* is a set of mathematical equations that specify how a system changes over time. The various patterns and processes that emerge from this set of equations rely on a technical language originally developed in the fields of mathematics and physics. The concepts derived from this mathematical framework constitute the principles of dynamic systems approaches. The terms that are most commonly associated with this framework are attractors, repellers, state space, perturbations, bifurcations, catastrophe, chaos, hysteresis, complexity, nonlinearity, and far from equilibrium. Thus, what we refer to as dynamic systems theory or dynamic systems principles is a *metatheoretical* framework that encompasses a set of abstract principles that have been applied in different disciplines (e.g., physics, chemistry, biology, psychology) and to various phenomena (e.g., lasers, ant colonies, brain dynamics) at vastly different scales of analysis (from cells to economic trends and from milliseconds to millennia).

Consistent with developmental DS theorists (e.g., Fogel, 1993; Lewis, 2000; Thelen & Smith, 1994, 1998), we use the term dynamic systems to refer to the systems themselves (not the equations) that change over time. DS principles provide a framework for describing how novel forms emerge and stabilize through a system's own internal feedback processes (Prigogine & Stengers, 1984). This process is known as *self-organization* and refers to the spontaneously generated (i.e., emergent) order in complex, adaptive systems. In fields as various as physics (e.g., Haken, 1977), chemistry (e.g., Prigogine & Stengers, 1984), biology (e.g., Kauffman, 1993), and neuroscience (Freeman, 1995), DS principles have proven essential for providing process-level accounts of the structure and organization of system behavior and changes in that structure over time (Lewis & Granic, 2000).

DS principles resonate with most systems concepts in general. DS approaches to development emphasize the multiple reciprocal interactions among system elements that are hierarchically nested and mutually influential. The context or ecology in which the system is embedded is critical for understanding a dynamic system's behavior. Also consistent with various systems perspectives, development is conceptualized as movement toward greater levels of complexity through the interplay between positive and negative feedback cycles (Lewis & Granic, 1999b).

As will become clear from our selection of methods, we are most strongly influenced by the pioneering work of Esther Thelen, Linda Smith, Alan Fogel, Marc Lewis, and

Paul van Geert, developmental psychologists who brought DS principles to the attention of the field at large. Because our focus is on methods specifically, a thorough theoretical discussion of DS concepts and their relevance to developmental science is precluded; the reader is strongly encouraged to supplement the current theoretical introduction with reviews by Thelen and Smith (1994, 1998), Fogel (1993), and Lewis (2000). In the following discussion, we highlight some key principles and then move on to their methodological implications.

State Space, Attractors, and Dynamic Stability

Dynamic, self-organizing systems share several key properties, some of which have already been mentioned. One key feature of open systems is that, although theoretically they have the potential to exhibit an enormous number of behavioral patterns, they tend to stabilize in a limited range of these possibilities. Stable patterns emerge through feedback among many lower-order (more basic) system elements; these emergent patterns are referred to as *attractors* in DS terminology. In real time, attractors may be understood as absorbing states that "pull" the system from other potential states. Behavior moves in a trajectory across the state space toward these attractors. Over developmental time, attractors represent recurrent patterns that have stabilized and are increasingly predictable. As noted by Thelen and Smith (1994), all developmental acquisitions can be described as attractor patterns that emerge over weeks, months, or years.

As recurring stable forms, attractors are often represented topographically as valleys on a dynamic landscape (see Figure 22.1). The deeper and wider the attractor, the more likely it is that behavior falls into it and remains there, and the more resistant it is to small changes in the environment. *Repellers*, or states that the system tends to avoid or be repelled from, are represented as hills on this landscape—states in which the system cannot rest. As the system develops, a unique *state space*, defined as a model of all possible states a system can attain, is configured by several attractors and repellers. Critically, living systems are characterized by *multistability* (Kelso, 1995); that is, their state space (i.e., behavioral repertoire) includes several coexisting attractors. Contextual constraints probabilistically guide behavior toward a particular attractor at any given moment in time.

As we will see later, the concepts of state space, attractors, and multistability have informed several research designs and methodologies in recent years. The operationalization of these principles, either graphically, math-

Figure 22.1 A state space with three attractors (the wells) and one repeller (the hill).

ematically, or heuristically, have helped DS researchers uncover previously undetected behavioral variability, as well as the processes by which this variability stabilizes into unpredicted, but nevertheless stable, attractor patterns.

Interrelations between Time Scales

DS researchers are fundamentally concerned with the interplay between different time scales. From a DS perspective, the same principles of change and stability can be applied at the moment-to-moment scale (real time) and to developmental time (weeks, months, years). The interplay between nested time scales is constant and reciprocal (Thelen & Smith, 1994, 1998). Self-organization at the real-time scale constrains self-organization at the developmental scale, which, in turn, constrains real-time behavior (Port & van Gelder, 1995). Thelen and Smith (1998, p. 593) elaborate:

Each behavioral act occurs *over time* . . . but every act changes the overall system and builds a history of acts over time. . . . Habituation, memory, learning, adaptation, and development form one seamless web built on processes over time—activities in the real world.

Research designs based on DS principles almost always measure behavior on at least two time scales. The manner and extent to which the two or more levels of analysis are related to each other are subsequently examined. Thus, DS-informed studies often involve collecting real-time, observational data over repeated sessions in a longitudinal design such that moment-to-moment behavioral patterns, and changes in those patterns, can be traced along a longitudinal trajectory (Lee & Karmiloff-Smith, 2002).

Hierarchically Embedded Levels of Organization

Dynamic systems are not only nested processes in time, they are also coupled hierarchically. Mechanisms in development may be defined at different levels of organization (e.g., physiological, emotional, behavioral, social), and these levels are thought to be embedded, linked by feedback processes, and mutually constraining. Especially important, DS theorists insist that no level of organization is any more “basic” or “primary” in terms of causality. Thus, for example, from a DS perspective, neural processes are accorded no higher causal privilege than psychological or social processes. Instead, “descriptions of change of many components are needed so that multilevel processes and their mutual interactions can be fully integrated. . . . Moreover, explanations at every level must be consistent and ultimately reconcilable” (Thelen & Smith, 1998, p. 596–597). This view of causality contrasts with most approaches in psychology (but see Cicchetti & Dawson, 2002b).

Rather than simple linear relationships, DS researchers often understand relations among multiple levels in terms of *circular causality* (Hakens, 1977). Circular causality suggests that interactions among lower-order elements provide the means by which higher-order patterns emerge, and these emergent attractors exert top-down influences to maintain the entrainment of lower-level components. Developmental psychopathologists, particularly those in the neurosciences, have recently become interested in understanding how different levels of analysis can shed light on typical and atypical development (Calkins & Fox, 2002; Cicchetti & Dawson, 2002a; Nelson et al., 2002). The DS metatheoretical framework, with concepts such as circular causality, may help researchers organize their findings and parsimoniously integrate the various theories about different levels into one coherent model. Indeed, it is likely that

common dynamic principles of self-organization govern different levels of organization (e.g., neural, cardiac, emotional, behavioral, societal); if this is so, then synergistic DS methods that can be applied similarly at different levels of analysis will provide a powerful means by which integrative models can be developed and empirically supported. The extent to which real-time and developmental time scales are interrelated and hierarchical levels of organization are embedded is further clarified when considering perturbations and their relation to phase transitions.

Perturbations, Phase Transitions, and Nonlinear Change

Through the amplification properties of positive feedback, nonlinear changes in the organizational structure of a dynamic system can be observed. As shown in Figure 22.2, these abrupt changes are referred to as *phase transitions*; they occur at *points of bifurcation*, or junctures in the system's development. At these thresholds, small fluctuations have the potential to disproportionately affect the interactions of other elements, leading to the emergence of new forms. Novelty does not have to originate from outside the system; it can emerge spontaneously through feedback within the system. During a phase transition, systems are extremely sensitive to *perturbations*. Between these points, however, self-organizing systems tend toward coherence and stability.

Figure 22.2 Alternative developmental trajectories. Phase transitions occur at regular junctures in development. Increased variability at phase transitions is shown in magnified segment. *Source:* From “A Dynamic Systems Approach to Cognition-Emotion Interactions in Development” (pp. 159–188), by M. D. Lewis and L. Douglas, in *What Develops in Emotional Development?* M. F. Mascolo & S. Griffins (Eds.), 1998, New York: Plenum Press.

Phase transitions are characterized by interrelated changes in real and developmental time. In developmental time, periods of stability and relative predictability are followed by a period of disequilibrium in which established patterns are destabilized. After this period of flux, developmental systems restabilize and settle into new habits of interactions. Corresponding to this developmental profile, real-time behavior during a phase transition is more variable, flexible, and sensitive to perturbations; behavior may change from one state to another frequently and is less likely to settle in any one state for very long (Thelen & Ulrich, 1991). However, before and after the phase transition, real-time behavior is far less variable; only a small number of behavioral states are available to the system, and once the system settles into one of these stable patterns, it tends to remain there for an extended time period (e.g., Thelen & Smith, 1994; van der Maas & Molenaar, 1992; van Geert, 1998a).

DS researchers have used the concept of perturbations on a real-time scale as an empirical design innovation to test the relative stability of observed behavioral patterns. Perturbations have the potential to abruptly “push” the system from one stable pattern to another (Fogel, 1993; Thelen & Smith, 1994). But this is only a potential—whether and how a system becomes reorganized is determined by its underlying structure. A perturbation can be considered a focal aspect of environmental context, and sensitivity to perturbations (which typifies phase transitions) is a special case of the more general sensitivity of dynamic systems to their contexts—a sensitivity that changes with system development gradually or more suddenly. Thus, context sensitivity for DS researchers is not just “a form of jargon for anything environmental, as if invoking the term suggests compliance with current scientific and conceptual canons” (Boyce et al., 1998, p. 145). DS researchers systematically observe changes in behavior, as it varies with contextual forces, to infer the underlying structure of the system (e.g., Fogel, 1993; Granic & Lamey, 2002; Lewis & Granic, 1999b, 2000; Thelen & Smith, 1994; Thelen & Ulrich, 1991).

On a developmental scale, principles of nonlinear change, phase transitions, and perturbations have been most often used for the explicit purpose of studying the structural profile of developmental transitions (e.g., Fogel & Thelen, 1987; Granic, Hollenstein, Dishion, & Patterson, 2003; Lewis, 2000; Lewis & Granic, 2000; Thelen & Ulrich, 1991; van Geert, 1991, 1994). Neo-Piagetian scholars such as van der Maas and Molenaar (e.g., 1992) have used a particular type of dynamic model, the cusp-catastrophe model, to represent the nonlinear nature of stage transi-

tions. Borrowing from Gilmore (1981), they suggest a number of criteria or “flags” that can be used to operationalize a transition. Among the transition flags are a sudden jump from one parameter value to another, evidence of hysteresis (i.e., when the same conditions elicit different behaviors, depending on the immediate prior history of the system), anomalous variance, and an increased sensitivity to perturbations. Transitions in motor, cognitive, linguistic, and socioemotional development have been successfully modeled by the application of variants of these flags (Case et al., 1996; Lewis et al., 1999; Lewis, Zimmerman, Hollenstein, & Lamey, 2004; van der Maas & Molenaar, 1992; van Geert, 1991, 1994). Structural changes in parent-adolescent interactions at the early adolescent stage transition have also been shown to exhibit the properties of a phase transition (Granic, Dishion, & Hollenstein, 2003; Granic, Hollenstein, et al., 2003).

Many of the DS concepts described here are clearly resonant with other systems views. But as a point of distinction, we suggest that there are four principles that are central to the DS framework which are either neglected or less emphasized in other approaches and which hold great promise for new empirical directions in developmental psychopathology. First, DS theory is primarily concerned with the emergence of novelty through the process of self-organization, whereas, with some notable exceptions (Ford & Lerner, 1992), most of the emphasis in more general systems views is on mechanisms of stability (i.e., negative feedback processes; for examples, see cybernetic models; Granic, 2000; Lewis & Granic, 1999a). Second, although systems views may acknowledge the nonlinear nature of change in developmental systems, this is the hallmark principle of DS approaches to development, and it has led to the exploration of radical new strategies such as catastrophe theory (e.g., van der Maas & Molenaar, 1992), developmental growth curve modeling (van Geert, 1991, 1994), and the study of phase transitions (e.g., Thelen & Smith, 1994; Thelen & Ulrich, 1991). Third, variability represents critical information in DS research. Conventionally, variability in developmental data has been seen as the result of measurement error and, thus, a source of noise that should be minimized. DS theorists make a radical departure from this approach: Variability is considered a rich source of information, indexing impending change and “the essential ground for exploration and selection” (van Geert & van Dijk, 2002, p. 345). Methods that tap changes in variability are a mainstay of DS researchers (e.g., Thelen & Ulrich, 1991; van Geert & van Dijk, 2002). Finally, DS theorists are fundamentally concerned with the interrelations between time scales of development and put a great deal of

emphasis on understanding the unfolding patterns of real-time behavior (Thelen & Smith, 1998). This final principle is critical in terms of its methodological implications, and it is most often ignored in other systems frameworks.

In the following sections, we describe a number of dynamic systems approaches to research designs and measurement strategies. To limit the scope of our review, we do not discuss the exciting work emerging in the neurosciences (a field that has long embraced the principles of self-organization). This work is clearly relevant to developmental psychopathologists, and the reader is referred to the neuroimaging methods detailed in the second volume of *Developmental Psychopathology* (2nd edition). We also spend less time proportionally on the mathematical modeling techniques than the graphical, descriptive, and statistical ones because we believe that the latter group of methodologies are generally more accessible and may ultimately prove more appropriate for the types of research questions put forward by developmental psychopathologists.

We first review some general DS-informed research design concepts and strategies put forth by Thelen and her colleagues (e.g., Thelen & Smith, 1994; Thelen & Ulrich, 1991). Next, we discuss the types of data most suitable for DS analyses. We then provide a list of graphical techniques and quantitative strategies appropriate for the analysis of real-time and developmental data; these descriptions are supplemented with actual or hypothetical examples relevant to developmental psychopathologists. We also highlight the limitations inherent in some of the techniques and argue that a newly developed DS methodology, state space grid analysis, may help address a number of these weaknesses. The last part of this chapter provides a detailed description of the state space grid technique, which combines graphical methods with statistical analysis in a way that maintains fidelity to DS concepts. We provide several examples of programs of research and individual studies that have used variations of this approach.

RESEARCH DESIGN STRATEGIES INFORMED BY DS PRINCIPLES

Thelen and her colleagues have explicitly laid out a methodological strategy for developmental psychologists interested in dynamic analyses (Thelen & Smith, 1994, 1998; Thelen & Ulrich, 1991). Their strategy involves the following six steps.

Identify the Collective Variable of Interest

A collective variable must be an observable phenomenon (not a construct or latent variable) that captures the coordination of the elements of a multidimensional system. Because Thelen and Ulrich (1991) were interested in motor development, they chose the phasing of alternating steps as the collective variable that condensed the many aspects of interlimb coordination. Changes in this collective variable can then be tracked over developmental time. This is the first challenging step; unlike in physical systems, it is difficult to identify a collective variable in psychological systems. Extensive developmental observations and experiments are recommended as a first step toward this goal. An example relevant to developmental psychopathologists might be the observed intensity of a child's oppositional behavior—a collective variable that may capture the coordination of mood states, arousal level, appraisal processes, and so on (these processes themselves would need to be assessed in multiple contexts).

Describe the Attractors for That System

This step involves mapping the real-time trajectory of the collective variable in various contexts across different developmental periods and identifying its relative stability. Thus, the contexts in which a child's oppositional behavior is most stable can be identified (e.g., with a parent), as well as the contexts in which such behavior is less stable (i.e., more easily changed), is never observed, or is rarely observed. High stability indicates an attractor state.

Attractor states may be tested by examining the variability of the collective variable given particular contexts (e.g., How often does the child become oppositional in response to a request to clean up at home versus at school?). Additional features can help identify attractors as well. First, an attractor may be present if behavior takes a relatively short time to return back to the state once it has left it (latency to return to the attractor is short). Second, behavior tends to stay in an attractor for longer durations than other states. Third, it should take a much larger perturbation to move behavior out of a strong attractor state relative to weaker attractors or other regions of the state space.

This last point is also a reminder that living systems exhibit multistability. The implication is that researchers should attempt to identify all or many of the attractors that are available to a particular system. Then the critical question becomes: What are the conditions under which behavior will gravitate toward one attractor versus an-

other? Returning to the oppositional child, most conventional approaches focus on describing and predicting the child's negative, destructive behavior. But a DS approach would map out not only the negative behavior attractors, but also the interested/engaged states, the joyful, and the neutral states and, especially important, the pathways to and from these attractors. Although these latter states may be weaker attractors, the goal would be to track the contextual conditions under which the child moves from more positive to more negative attractors and vice versa in order to get a better picture of the underlying dynamics of this child's behavioral landscape.

Map the Individual Developmental Trajectories of the Collective Variable

This step requires collecting observations at many time points in a longitudinal design (also see Fogel, 1993). The density of time samples depends on the developmental period in question (i.e., in infancy, weekly observations may be needed, whereas in late childhood, data collected monthly might suffice; Fogel, 1993). Then developmental profiles can be graphed on a case-by-case basis and the similarities and differences among profiles can be described. Stable (i.e., fixed or cycling) segments of the time series denote an attractor. At this stage, the multifinality and equifinality of developmental trajectories can be discovered. Some developmental profiles may start out looking similar, and then, from very small differences that become amplified, trajectories may diverge. Other developmental profiles may show the opposite pattern, of different initial conditions being pulled toward a particular attractor. The key at this stage is to create *individual* profiles rather than aggregate across subjects; otherwise, the variability inherent in developmental processes will be obscured.

As described in more detail later, an alternative to averaging developmental profiles is to cluster individual trajectories into groups that share profile characteristics (Hollenstein, Granic, Stoolmiller, & Snyder, 2004). In developmental psychopathology, a similar point has been emphasized by researchers doing case-based, or person-oriented, analysis (e.g., Bergman & Magnusson, 1997).

Identify Phase Transitions in Development

As described earlier, transitions in development are characterized by increased variability, a breakdown of stable patterns, and the emergence of new forms. The various ca-

tastrophe flags described earlier can help researchers identify points of transition. Transition periods are critical to mark because they allow researchers to access and manipulate mechanisms underlying change. This point is particularly relevant for developmental psychopathologists interested in clinical interventions. For instance, there may be normative stage transitions in children's development during which, as a result of normal maturational processes, the coordination among system elements begins to break down, previous attractors are destabilized, and there is an increased potential for new patterns to emerge (e.g., Granic, Hollenstein, et al., 2003; Lewis & Granic, 1999b; Lewis et al., 1999; Lewis et al., 2004). Clinical interventions may have their greatest impact if they are targeted at these sensitive periods.

The idea of fluctuations at phase transitions is not new to developmental psychopathology, although it has rarely been pursued empirically. One fascinating example comes from a study conducted by Inhelder (1976), who found that some mentally retarded children's skill performance oscillated between various stage levels prior to reaching a new stage. Interpreting these findings, Cicchetti (1990) suggested two possibilities: The processes accounting for these children's development may simply be different from those of normal children, or, more intriguingly, "their oscillations are universal phenomena that become visible only in retarded children because of the slower nature of their development" (p. 16; see also Cicchetti & Sroufe, 1976).

Bertenthal (1999) further emphasizes the importance of variability at phase transitions. He suggests that variability is not just an index of change, but actually helps *drive* change. According to Bertenthal, "Variability offers flexibility, which drives development following Darwinian principles. Principles of variation and selection cause successful behaviors to be stored and repeated more frequently than the less successful" (also see van Geert & van Dijk, 2002, p. 343; cf. Thelen & Smith, 1994). The theoretical implications for understanding intervention effects are compelling. Successful interventions may *induce* a phase transition during which behavioral, cognitive, and affective variability increases, providing the fertile ground from which more positive, or less distressing, patterns can be selected, repeated, and potentially stabilized. This possibility can be empirically verified by using simple descriptive statistics (e.g., looking for an increase in standard deviations and variance and a breakdown of correlations; additional measures of variance are described later) or more formal techniques (described in the section on state space grids).

Identify Control Parameters

In DS language, control parameters are the "agents of change." The purpose of tracking the collective variable across different contexts and developmental transition points is to ultimately identify the mechanisms underlying processes of change. Control parameters are not simply independent variables (although they can be considered a special type of these). Usually, independent variables are static measures that are assumed to have a linear effect on outcomes. Control parameters are better understood as mediators with special properties; continuous and small changes in the values of these parameters can result in abrupt threshold effects on a collective variable. Moreover, these nonlinear changes occur at different values depending on whether the control parameter is increasing or decreasing. For example, through fine-grained longitudinal observations, Thelen and Ulrich (1991) were able to identify overall changes in muscle mass as the control parameter that was related to improvements in infants' treadmill stepping. In many areas of developmental psychopathology, however, this step is the most difficult, because psychological systems are incredibly complex, and the problem of identifying and manipulating one or very few causal mechanisms is often insoluble. Moreover, a control parameter may not always be something that *can* be manipulated (e.g., temperament, parental depression). Nevertheless, DS researchers urge us to at least keep the concept in mind.

Manipulate Control Parameters to Experimentally Generate Phase Transitions

Despite its difficulty, this suggestion is a familiar one to many developmental psychopathologists. Simply put, once a causal factor has been inferred from careful descriptive analysis, it should be experimentally manipulated to examine whether it does indeed trigger the expected shift in behavior. In this respect, intervention studies are an exceptional avenue for testing the role of specific control parameters in developmental psychopathology (see Dishion, Bullock, & Granic, 2002; Dishion & Patterson, 1999; Eddy & Chamberlain, 2000; Forgatch & DeGarmo, 1999).

One of the best examples of following this proposed strategy comes from the work on the etiology and treatment of aggressive behavior. For instance, based on decades of microsocial observational studies with families, coercion has been identified as a mediating causal mechanism underlying the etiology of childhood aggression (e.g., Patterson, 1982; Patterson, Reid, & Dishion, 1992). To confirm this supposition experimentally, Forgatch and DeGarmo

(1999) investigated the impact of a randomized control intervention that aimed to decrease the rate at which parents engaged in coercive interchanges. Results confirmed that, indeed, changes in coercion resulted in decreases in children's aggressive behavior. From a DS perspective, parental discipline strategies, for example, could have been the control parameter that was adjusted through the intervention (i.e., coercion decreased).

Despite the advantages of Thelen and colleagues' approach, many researchers are likely to experience some problems with implementing their general strategy. First, it requires collecting continuous time-series data (e.g., physiological data, behavioral observations coded in real time); this type of data is time-consuming and expensive to collect. More important, time-series data may not capture the type of information pertinent to many developmental psychopathologists. Second, and related, unlike motor or cognitive development, in which some skill or task performance increases or decreases quantitatively over time, psychopathology may not involve such graded changes (cf. Lewis & Granic, 1999b; Lewis et al., 2004). Instead, the development of psychopathology may be better characterized as emergent patterns of interconnected changes in different domains (e.g., biological, cognitive, emotional) that are nonlinearly related to one another and change qualitatively as well as quantitatively (i.e., it is often categorical or ordinal). We address this issue at greater length when we discuss state space grid analysis and the limitations it addresses in this regard.

SUITABLE DATA FOR DS ANALYSES

There are several types of data that developmental psychopathologists collect that are appropriate for DS analyses. Because a DS perspective is fundamentally about changes in time, the most important data characteristic is multiple measurements over time. Thus, questionnaire data collected at one time point would be inappropriate for tapping dynamic processes (e.g., Cummings et al., 2000). Next, we list the four types of data that lend themselves most easily to DS analyses and name some examples of analytic techniques that can be conducted. These techniques are then explained in more detail in the following section. Table 22.1 lists the techniques and the appropriate data types for each and provides some (nonexhaustive) examples of empirical papers that have applied the various DS methods.

Observational data—continuous: Includes data obtained in time units less than 1 second; these data often comprise physiological measures. The density of data points

allows for the more sophisticated techniques adopted from the natural sciences, where this type of data is most common. These techniques are often based on time-series analysis and include the domain of elaborate mathematical models based on coupled equations and dynamical catastrophe models. Quantitative measures of chaos—Lyapunov exponents, entropy, correlational dimensions, and so on—can also be derived from such continuous data. Furthermore, all of the methods available to the other data types are available with this kind of data, either as time-series or summaries of time-series.

Observational data—discrete: Includes live and taped observational data that are converted to codes along time units as small as 1 second. These codes can represent the sequence of behavior for one or more subjects and are typically inappropriate for time-series techniques unless they have a sufficiently large number of data points. By applying DS graphical techniques such as state space grids, Karnaugh maps, and phase plots, the temporal patterns embedded in the temporal sequence can be uncovered. These data can be used to identify attractors, perturbations, phase transitions, and other DS patterns.

Longitudinal data—short: Includes, for example, hourly/daily/weekly self-report measures (e.g., diary or beeper studies), repeated phone interviews, or repeated observational sessions (e.g., therapy sessions). The time points may be frequent enough to allow the use of some of the real-time techniques available to the first type of data or may be analyzed using techniques applicable to developmental-time data (Type 4).

Longitudinal data—long: Includes any combination of the previous data types collected at different time points that may span weeks, months, or years. The main distinction from data type 3 is the time span between first and last measurements. Data collected in three or more waves is often used to depict change, growth, or intervention effects, and a variety of DS methods including state space grid analysis, dynamic growth modeling, developmental profile analysis, and catastrophe modeling can be applied. Developmental phase transitions are detectable through the application of these techniques.

DS METHODS

In the following two sections, real-time and developmental methods are discussed. A number of these techniques have been developed specifically for testing DS-based hypotheses. Other methods were not designed specifically to ad-

TABLE 22.1 Summary of Dynamic Systems Techniques and Concepts and Examples of Studies That Have Applied These Techniques

Techniques	DS Concept	Examples
Real Time		
Case studies	Self-organization	Fogel (1990, 1993)

dress DS questions; however, they may be quite fruitful in this regard. Moreover, perhaps the greatest advantages of conducting DS research is in combining methods at different scales of analysis in one study.

Real-Time Measures

As most teachers of research methods and statistics in general insist, eyeballing your data is an important part of the analytic procedure. For DS researchers, graphical techniques provide the core of their analytic armament. Perhaps because dynamic systems theory is a descriptive framework and because it aims to describe phenomena in geometric terms (recall our discussion of behavioral trajectories on a state space), plotting data is the mainstay of DS researchers (Norton, 1995). As described later, a number of these real-time and developmental time graphical methods can be complemented with various quantitative tools. We have grouped the following methods under the rubric of real-time methods because that is how they have tended to be applied. But it is important to note that because the same principles of self-organization apply at different time scales, many of these techniques can be adapted easily to study phenomena in developmental time.

Case Studies

Perhaps the one common recommendation DS researchers offer is to start with fine-grained, real-time observations of the phenomenon of interest and follow this behavior across a significant developmental period. One of the most basic first steps toward this end is the careful description of case studies. Fogel's (e.g., 1990, 1993) research on mother-infant relationship processes is exemplary in this respect. His "microgenetic" research relies heavily on detailed descriptions of videotaped interactions as they proceed in real time. He uses these case histories as a "means to seek patterns in sequences of action in a context, in both real and developmental time scales" (1990, p. 343). Metaphors based on DS principles serve as guides for identifying dynamically stable dyadic patterns ("frames") and changes in those patterns across development.

Although these narrative descriptions are rich in detail and provide ample fodder for generating hypotheses, they are intentionally not quantified at this stage. As such, this method does not address developmental psychopathologists' search for quantitative techniques to test their conceptual models. To quantify impressions from case studies and statistically test hypotheses, Fogel and his colleagues have used a number of techniques (for a review, see Lavelli, Pantoja, Hsu, Messinger, & Fogel, in press), including sim-

ple descriptive statistics, individual growth curve modeling (Fogel, 1995; Hsu & Fogel, 2001), and event history analysis (Hsu & Fogel, 2001) to measure the emergence, strength, and dissipation of parent-infant attractors. These methods are discussed in later sections of this chapter.

Time-Series Analysis

The group of methods that fall under time-series analysis offer some useful approaches to characterizing the real-time behavior of dynamic systems. The methods include visual representations as well as simple statistics that can be used to examine the qualities and predictive power of hypothesized attractor patterns. To illustrate the utility of this approach, we summarize the rationale, time-series procedures, and results from a study we have recently completed using data from antisocial and normal friendship interactions.

Past research suggested that antisocial adolescents can be distinguished from their prosocial counterparts by the extent to which they engage in reciprocal deviant talk (e.g., talk about stealing, lying; Dishion, Capaldi, Spracklen, & Li, 1995; Dishion, Spracklen, Andrews, & Patterson, 1996; Dishion, Eddy, Haas, Li, & Spracklen, 1997). Observational studies showed that antisocial peers had a higher mean duration of deviant talk (or "rule-break" talk) than prosocial peers. Central tendency measures, however, do not speak directly to the processes underlying these interactions. Moreover, they obscure potentially critical temporal patterns. To come closer to a process-level explanation, we began by conceptualizing deviant talk as an attractor for antisocial, but not prosocial, peers (Granic & Dishion, 2003). Our interest was not in examining whether one group showed more deviant talk than another, but whether, over the course of an interaction, antisocial adolescents became stuck in an antisocial talk attractor. That is, did they become increasingly engrossed in topics organized around deviancy? One way to explore this hypothesis was to examine whether, as the interaction unfolded and antisocial dyads repeatedly returned to talking about deviant topics, they also spent increasingly more time in that deviant pattern. Time-series procedures were well-suited for our purposes.

Deviant (or rule-break talk) and normative talk were coded continuously from videotaped interactions between best friends. Time-series plots were derived for each dyad, with the duration of each deviant talk bout on the y axis and each successive bout represented along the x axis (Figures 22.3 and 22.4). The slope of that time series (i.e., the standardized beta) was then calculated using simple regression analysis. Slope is one parameter that can be identified from a time series; others include cyclicity (number of cycles in a series, length of cycles) and autocorrelation.

Figure 22.3 Example of a time-series for an antisocial youth with a positive rule-break bout slope.

We used the slope measure in a somewhat unique way to highlight a key DS principle. If deviant talk indeed functioned as an attractor for antisocial youth, then we expected to see a time series that showed a positive slope, as exemplified in Figure 22.3. If it was not an attractor for a dyad, then we expected to see a time series with either a flat or a negative slope, as shown in Figure 22.4. Thus, each participant was assigned a deviant-talk slope value, and these values were then used in regression analyses to predict antisocial outcomes 3 years later.

The results are summarized in Table 22.2 As hypothesized, the attractor index (the slope of deviant talk bouts)

Figure 22.4 Example of a time-series for a normal adolescent with a negative rule-break bout slope.

predicted serious authority conflict (e.g., number of arrests, school expulsion) and drug abuse 3 years later. These results were particularly strong because they remained statistically significant even after controlling for arguably the three most predictive risk factors in childhood: prior deviant behavior, family coercion, and deviant peer associations in childhood. We also showed that the mean duration of deviant talk bouts was not sufficient to predict these outcomes. Thus, these findings showed that reconceptualizing deviant talk as an attractor is not simply an exercise in relabeling; there are specific hypotheses that are engendered by applying this approach. From a DS perspective, although the frequency and amount of time spent talking about deviant topics is important, even more critical is the process by which dyadic behavior continues to be drawn toward, and held, in this deviant pattern. Both antisocial and prosocial peers discussed deviant acts and breaking rules. *It was the dynamic (time-based) characteristics of these conversations, as revealed by a simple time-series analysis, that differentiated antisocial and normal friendships.*

A similar analytic approach was used by Bakeman and Gottman (1997). They analyzed data from marital couples' interactions using this time-series technique, except they plotted the interevent interval between successive displays of negative affect (i.e., the time between one negative affect and the next, across the interaction). They showed that, for distressed dyads, the time between each negative affect display became shorter and shorter over the course of the conversation (i.e., return time to the attractor became shorter over the interaction). Thus, negative affect was an absorbing state for distressed, but not happily married, couples.

Phase Plots

Phase portraits generally are state spaces filled with behavioral trajectories. More often, these plots are called phase plots when the variables being plotted are continuous, such as velocity and displacement of a pendulum. With the continuous data sometimes used by developmental psychopathologists, it is possible, for example, to create plots that depict the magnitude of change against the rate of that change (e.g., with galvanic skin response or heart rate data).

For the more common types of discrete, turn-taking (e.g., conversational turns) observational data that developmental psychopathologists collect, phase space can be "reconstructed" by plotting behavior at time t against behavior at time $t + 1$ (sometimes called a lag-1 plot). These types of plots can alert researchers to different types of attractor states (i.e., cyclical, fixed point, oscillating) and, thus, uncover process-level information not otherwise

TABLE 22.2 Regression Results Predicting Adolescent Authority Conflict and Substance Abuse in Midadolescence from the Strength of the Deviant Talk Attractor in Early Adolescence, after Controlling for Previous Child Deviancy, Family Coercion, and Deviant Peer Affiliation

Steps in Regression	Antisocial Behavior		Substance Abuse	
	R^2 Change	Total R^2	R^2 Change	Total R^2
1. Child deviancy	.28 ^a		.16 ^b	
2. Child family coercion	.02	.30	.02	.18
3. Child deviant peer affiliation	.07 ^b	.36	.06 ^c	.24
4. Attractor strength (slope of deviant talk)	.05 ^b	.41	.06 ^c	.30

^a $p < .001$ ^b $p < .01$ ^c $p < .05$.

accessible. For example, in the study previously described, Granic and Dishion (2003) initially used phase plots to explore the dynamic patterns underlying adolescent friendship interactions. From the time series previously described, a “floating window” was used to plot each value of the time series such that the duration of the deviant talk bout at time t was represented on the x axis and the duration value at time $t + 1$ was plotted on the y axis.

The plots look much like scatter plots of first-order autocorrelations except that a trajectory connects successive points; thus, the temporal integrity of the interaction is maintained. Figure 22.5 is an example of an antisocial dyad’s phase plot. Much like the time-series plots indicated, the phase plot shows that this dyad began with very short durations in the deviant talk pattern (points 1 to 3), but, over time, they spent more and more time in this state (points 49 to 52). The plot suggests that for this antisocial dyad, antisocial talk was an attractor state, the strength of which held the dyad in the pattern for longer and longer time periods. Eventually, this dyadic system may move to-

ward continuous deviant talk. There are several other possible patterns that phase plots can exhibit. For example, a large proportion of prosocial dyads showed a relatively “random” phase plot similar to the example presented in Figure 22.6, suggesting that deviant talk was not an attractor for these peers.

Event History Analysis

As can be seen from the previous examples, and others to follow, it is not always necessary to invent new methods to explore DS-inspired hypotheses. Another method that can help researchers explore the different characteristics of attractor processes is event history analysis. A variant of survival analysis and Cox regression models, event history analysis calculates transition rates (also called hazard rate or latency to recurrence) of state changes in categorical time series (Allison, 1984; Blossfeld & Rohwer, 2002). The rate of transition in and out of a behavioral state (e.g., tantrum, laugh) can be interpreted as an index of attractor strength. Several other measures, including the frequency,

**Figure 22.5** Phase plot for an antisocial dyad.**Figure 22.6** Phase plot of a prosocial dyad.

duration, total time, and the time since the last occurrence of the behavior, can be included in these models to determine the absorbing quality of a hypothesized attractor. Furthermore, time-invariant (e.g., gender) and time-varying (e.g., changes in context) covariates can be added to these models as predictors of the transition rate.

Figure 22.7 shows a schematic diagram of an interactive sequence. The bottom plot line represents the time line of events being modeled. In this case, there are only two states possible: in the “proposed” attractor or out of that state. This example illustrates a dichotomous response set, but it is not necessary for event streams to be binary for event history analyses; multiple states can be modeled as competing risks. The three episodes in this example correspond to the start and end times of the behavior of interest. The first episode lasts 14 seconds, the second episode lasts 18 seconds, and the third is 14 seconds long. With just this information it is possible to model the probability of transitions into the attractor as one instantaneous rate, and the duration since the last episode can be added into the model as a predictor.

Presumably, whatever behavior is being researched does not occur in a vacuum. There is the nature of the task at hand, the influence of other people, and even factors unique to each individual that must be considered. Thus, as shown by the time-varying covariates (upper two lines) in Figure 22.7, more elaborate models can tease apart the relative contributions of various covariates to the recurrence of a particular behavior. For example, Snyder, Stoolmiller, Wilson, and Yamamoto (in press) used event history models in a study of emotion regulation in early childhood. The events of interest were children’s anger episodes while interacting with a parent over the course of an hour in a variety of tasks on two separate occasions. They ran two

models. The first analyzed the time it took until the first display of anger, and the second modeled the time between repeated displays of the child’s anger. For these models, Snyder et al. included time-invariant effects of the child’s gender, ratings of child antisocial behavior, and parental discipline (as well as which of several observers coded the session). Time-varying covariates included the activity or task in which the dyad was involved, the parent’s “negative process” behavior, the cumulative frequency of the parent’s negative process events, and the session time.

In the first multivariate model (time to first anger display), only the parent’s negative process and the cumulative frequency of parent negative process were significant. The child’s anger was 4 times more likely to occur when the parent was in a negative process state. In the second multivariate model (repeated anger displays), because the power increased substantially due to the greater number of data points, all predictors were significant. There was one very interesting interaction effect wherein the accumulation of the parent’s negative process throughout the session increased the probability that subsequent parent negative process behaviors would elicit child anger. Thus, these results may be an indication of a dyadic, rather than an individual, attractor that exists for anger displays. A follow-up to this study could include collapsing the parent and child behaviors into one categorical stream and using an event history model to explore the possible effects on mutual anger displays.

The primary advantage of event history analysis is the versatility of the modeling procedures. These models can be run on individuals or pooled across an entire sample. It is not only the potential of identifying predictors of attractor strength that is the appeal for DS researchers but the fact that *time* itself can be used as a predictor. Probably the most difficult process of event history analysis is restructuring data into the appropriate format. Despite this difficulty, we expect that event history analysis will be used with increasing frequency as a method to model attractor dynamics.

Fourier analysis or spectral decomposition can be used for finding periodicities (i.e., cyclic patterns) in time-series data such as those used in phase plots. In general, this procedure treats a time series as a conglomerate wave form, breaks it down into a collection of pure waves (each of uniform frequency), and identifies the most prominent waves (Schroek, 1994). Newtonson (1994, 1998) has used this method to analyze the coupled dynamics of dyadic interactions. The relative amplitudes and temporal synchrony of these “behavior waves” were associated with the degree of mutuality or competition in interpersonal relationships. In other applications, different types of attractors,

Figure 22.7 Schematic diagram of a behavioral interaction with some of the components that can be analyzed through event history analysis.

including oscillating and periodic attractors, can be identified. For behavioral scientists, however, this method has its limitations. Like all time-series procedures, it requires the researcher to collapse meaningful categorically coded observational data into one or very few continuous dimensions (e.g., Bakeman & Gottman, 1997). For example, most observational coding schemes used in developmental psychopathology (e.g., FPC: Dishion, Gardner, Patterson, Reid, & Thibodeaux, 1983; SPAFF: Gottman, McCoy, Coan, & Collier, 1996; MAX: Izard, 1979) code discrete behaviors such as “contempt,” “argue,” “belligerence,” and “whining.” To conduct Fourier analysis, these codes would have to fall along a single dimension (i.e., intensity of negativity). This type of collapsing is often either conceptually unfeasible or it is unappealing because of its oversimplification.

Karnaugh Maps

Inspired by synergetics, a type of dynamics developed by Haken (1977), Dumas, Lemay, and Dauwalder (2001) adapted this technique from Boolean algebra to study parent-child interactions. Karnaugh maps depict all possible combinations of up to four binary variables in one table or grid. A simple two-variable Karnaugh map is basically a 4-cell cross-tabulation of event frequencies with one dichotomous variable to each axis. Three- and four-variable maps are somewhat more complicated. Figure 22.8 shows a schematic 4-variable Karnaugh map. Each variable (*A*, *B*, *C*, and *D*) can have a value of 0 or 1, and each is displayed on one side of the square table (bottom, left, top, and right). Each cell in the map can be represented as a unique combination of the binary values of the four variables. Thus, a Karnaugh map is a state space of all possible states of the system and represents the relative frequencies in each state. Dumas and colleagues extended the application of these maps by plotting the transitions between states to depict temporal patterns across the space.

In their study, Dumas et al. (2001) plotted every minute of 6-hour home observations according to four parent and child dichotomous variables that included control, compliance, and aversive and positive behavior. Each behavior was plotted according to the 4-variable configuration, and successive behaviors were connected by a trajectory. They were primarily interested in comparing the maps of clinically referred dyads with randomly selected controls. They analyzed the “recurring transactions” (i.e., attractors) that were found most frequently in each group and aggregated these findings graphically on one summary Karnaugh map. Their results showed differences in transactional patterns between the groups, mostly involving positive interactions

Figure 22.8 Schematic of a four-variable Karnaugh map. Each cell is a unique combination of four binary variables. The arrow shows a sample transition from one state, where only variable *D* is present (i.e., only *D* = 1), to the next state in time, where all four variables are present (i.e., all = 1).

and cycles of maternal control and child compliance. In addition to the graphical depiction of interaction sequences, the authors computed a “complexity index” that was designed to quantify each map on a continuum from completely deterministic to completely random. They found that all maps, regardless of group assignment, were neither random nor deterministic but somewhere in between.

Although this approach was unique and interesting (particularly from a methodological standpoint), from a DS perspective there is no reason to think that social behavior, especially in dyads with a rich history, is ever random or ever completely determined. Nevertheless, the complexity measure has a great deal of potential. For example, it might be used to determine whether stable coercive parent-child interaction patterns become less determined (i.e., the old attractor patterns break down) during developmental transitions such as puberty.

Karnaugh maps hold considerable promise for several reasons. First, because this method allows for the representation of behavior in up to four dimensions (five if you count time), a great deal of the complexity in interactional behavior can be nicely captured. The temporal quality of dyadic behavior is also maintained and can be tracked easily through visual inspection. Moreover, the systemic properties of dyadic interactions are kept intact, in contrast to conventional methods that often require analyzing each dyad member separately.

This methodology as applied to behavioral science, however, is very much in its infancy; thus, there are some limitations that may need to be addressed before Karnaugh maps can be applied to a broad range of behavioral data. One problem is that the adaptation of these maps to behavioral research requires data that can be collected or converted into dichotomous variables that occur concurrently. Developmental psychopathologists are often interested in data that cannot be meaningfully transformed into dichotomous values; continuous or categorical data cannot be adequately captured with these maps. Also, this method does not provide quantifiable tests of the strength of dyadic patterns, nor opportunities for comparing patterns. In this respect, the new developments in state space grid analysis may provide some promising avenues. Although the two approaches are not entirely similar, some of the quantitative measures that may be derived from state space grids may also be applicable to Karnaugh maps.

Coupled Equations

Most generally, this method refers to the use of paired equations derived from two synchronized time series that produce parameters that describe the underlying dynamics of a system. The use of coupled equations may involve mathematically demanding procedures and often requires fine-grained time-series data or simulated data. One particularly successful application in the field has been the work by John Gottman and colleagues, who have used coupled differential equations to model the dynamics of marital couples and to predict from those dynamics couples who will remain married or end by divorcing (Gottman, Coan, Carrere, & Swanson, 1998; Ryan, Gottman, Murray, Carrere, & Swanson, 2000). They have also used this method to study how peer interactions influence the behavior of developmentally delayed versus normal children (Gottman, Guralnick, Wilson, Swanson, & Murray, 1997) and parent-infant interaction (Gottman, Murray, Swanson, Tyson, & Swanson, 2002).

Gottman and colleagues' modeling procedures, based on mathematical biology, are an attempt to mathematically formalize theoretical assertions made by general systems theorists such as von Bertalanffy (1968). Their model itself represents a theory about the mechanisms and dynamics of marriage. Their approach is to model marital interactions using the mathematics of difference and differential equations. These equations express hypothesized mechanisms of change over time. Gottman and colleagues offer their model of marital interactions as a first attempt to create an explanatory theory of marriage; they recognize the value of cycling from theory development, to modeling, to

experiments, and back to theory development. As the authors comment, "The theory may be dead wrong, but it is precise" (Gottman et al., 2002).

The modeling process is guided by posing two questions: What are the steady states? and Which of these states are stable (i.e., the attractors) and which are unstable (i.e., repellers)? The first step is to set up the phase space such that each axis represents a variable corresponding to each participant. (This procedure is not the same as the one we described earlier in lag-1 phase plots.) The next step was to identify the steady states by graphing the "null clines," curves in phase space for which variables stay constant. These curves help to determine the steady states by partitioning the phase space into regions where changes in each variable are increasing or decreasing.

Gottman's technique uses a time series of coded observational data to create an equation for each person in the interaction. For this method, Gottman uses variables that are codes or categories of codes that fall along a single continuous dimension from very negative to very positive, with neutral in the middle. Equations are created to reflect the theoretical presumption that one person's behavior at time t is a function of his or her own behavior at time $t - 1$ as well as the other participant's behavior at time $t - 1$. Thus, there is an "uninfluenced" and an "influenced" factor in each equation that determines the behavior at each time t . The uninfluenced component is what each person brings to the interaction independent of the other. The uninfluenced set point can be thought of as a temperamental factor, which is assumed to be the attractor a person, left on his or her own, will eventually approach. Mathematically, this is denoted by a parameter that represents the rate of change toward the uninfluenced set point, also called "emotional inertia," plus a constant that is specific to the person. The influenced component is a mathematical function representing the other person's previous behavior. These functions can be used to plot curves that describe the degree of influence based on one assumption: Positive behavior influences positively and negative behavior influences negatively. Thus, the equations for a husband (H) and wife (W) are:

$$\begin{aligned}W_{t+1} &= r_1 W_t + a + I(H_t) \\ H_{t+1} &= r_2 H_t + b + I(W_t)\end{aligned}$$

where r is the emotional inertia, a and b are constants specific to the individual, and I is the influence function. These equations are then manipulated to estimate the parameters and to determine the uninfluenced and influenced set points. Plotting both of the null clines (the curves for which the values of the variables remain constant) in phase

space allows for the identification of stable steady states: the points where the two curves intersect.

Consider the example in Figure 22.9a, which shows bilinear null clines for a husband and wife. There is one positive and one negative stable state, or attractor, for this couple (the circles at the intersection of the two null clines). Over the course of the interaction, their behavior is drawn to one or the other of these attractors. One of the interesting uses of this modeling technique is its depiction of how a system exhibits sensitivity to initial conditions and how marriages can change over time. For example, situations at work may lead the husband to feel a lot of stress, and he may begin to express this stress in his interactions with his wife. This would be reflected in a change in the parameter b in the model that corresponds to the husband's uninfluenced state, or what he brings to the interaction. A change in this constant shifts his influence function to the left (Figure 22.9b), to the point where the positive attractor no longer exists. Thus, this type of modeling can distinguish between superficial change (i.e., a move to a different stable state) and deeper change (i.e., a fundamental change in the influence function that eliminates or adds a stable state to the marital couple's behavioral repertoire).

Gottman and his colleagues (2002) have used this basic model and more elaborated versions to identify mechanisms related to specific types of marriages. Some couples have only one stable steady state; if it is positive the marriage is "happy," if it is negative the marriage is "unhappy." Typically, the situation is more complex. Happy couples also tend to have both positive and negative attractors. In fact, high influence and high inertia couples tend to have multiple steady states and thus will most likely have at least one negative attractor. It may be the relative strengths of these attractors that best distinguish distressed and nondistressed couples.

Gottman and colleagues' (2002) approach to mathematical modeling seems to hold exciting potential for developmental psychopathologists who are interested in understanding social processes of various kinds. For example, their model can be easily adjusted to simulate interactions that have different types of power imbalances: parent-child interactions, therapist-client sessions, sibling interactions, bully-victim relations, and so on. Developmental psychopathologists have constructed detailed theoretical models that hypothesize specific influence functions among social partners (e.g., coercion processes in families with aggressive children, authoritative parenting and anxiety-disordered children). Gottman's approach challenges scholars in the field to translate these theories into mathematically specified mechanisms. This approach

Figure 22.9 Null clines and the stability of steady states. Steady states are circled and represented by the point at which the null clines intersect.

may be particularly rewarding if developmental principles can be formalized and included in these endeavors.

Nonlinear Dynamics

These methods are derived from mathematical procedures in physics and other sciences that aim to measure and model nonlinear phenomena (Abraham, Abraham, & Shaw, 1990; Heath, 2000; Norton, 1995). The simplest of these is nonlinear regression, wherein the parameters are exponential functions or the predictive combinations are not simply additive. Other applications from this area are those related to chaos theory (Newell & Molenaar, 1998). One can use nonlinear dynamic techniques to find the embedding dimension, entropy, determinism, recurrence, or fractal dimension of any time series of sufficient length and sufficient precision. This

class of techniques is typically applied to continuous time-series data (type 1), often physiological. For those developmental psychopathologists who are increasingly collecting this sort of data (e.g., heart rate, skin conductance, neural activity), this class of methods holds a great deal of promise, particularly if there are reasons to hypothesize nonlinearities. Moreover, there are many software packages available for free or at minimal cost that can calculate these measures for any appropriate time series. The challenge, therefore, lies not in the calculation but in the psychological interpretation of these measures.

There are a number of diverse applications of this class of techniques. One of the main reasons for using these methods is to determine the degree of orderliness, complexity, or predictability in the behavior of a given system. One recent example in developmental psychopathology comes from the work of Dishion, Nelson, Bullock, and Winter (in press). They applied a technique that calculated the degree of complexity of peer interactions, in the hopes of characterizing and differentiating prosocial versus antisocial peer interactions. The authors drew on information theory and applied Shannon's entropy measure (Shannon & Weaver, 1949) as an index of the degree of disorganization, uncertainty, or information in a dyadic interaction. In information theory, uncertainty and information are related because "information about an unknown event is more useful as one knows less about the event" (Wickens, 1989, p. 231). For example, if 100% of a set of communications is of one type (e.g., deviant talk), there is total certainty and no information is conveyed from one communication to another. This is a case of low entropy. Conversely, if there are a variety of types of communications and all are equally probable, then there is total uncertainty and a maximal amount of information is gained by finding out which event occurred. This is an example of maximum entropy.

Shannon's entropy measure is typically used with contingency tables where the values in each cell represent the probability of a different two-event sequence. A simple way to think of entropy is the average number of dichotomous decisions (yes/no) that need to be made to classify an event in that table (Wickens, 1989). Thus, in the previous example, the situation where only one event is observed would have a minimal entropy value of 1 because only one dichotomous decision is necessary to classify any event. Shannon's entropy is calculated as follows:

$$\text{Entropy} = H = \sum p_{ij} \left(\log_2 \left(\frac{1}{p_{ij}} \right) \right)$$

where p_{ij} is the conditional probability in the cell that is in row i and column j of a contingency table.

Dishion et al. (in press) used turn-taking observational data of boys interacting with their closest friend to calculate entropy. Their conversational turns were coded into five categories: negative engagement, directive, converse, positive engagement, and other. Thus, there was a 5×5 matrix of two-event sequences for each peer dyad. The frequencies in each cell of the matrix were used to calculate the conditional probabilities necessary for the entropy calculation. The findings from this study showed that all of the friendship dyads' interactions (regardless of whether or not they were antisocial) became more ordered (less entropic) over three time points: at 14, 16, and 18 years old. This finding in itself is compelling. It supports the DS view that development is characterized by increasing orderliness—a crystallization of interaction patterns. As relationships of all kinds develop, they stabilize and, thus, become more predictable over time. When the authors compared early-onset antisocial boys with prosocial boys, they found that antisocial boys' interactions corresponded to higher entropy scores, suggesting a more disorganized pattern, and were characterized by more deviant talk than interactions of the typically developing boys. These results may suggest that antisocial boys are less skilled than prosocial boys at carrying on a fluid, appropriately contingent conversation.

Some other potentially useful applications of this approach are found in clinical therapy research (e.g., Badalamenti & Langs, 1992; Burlingame, Fuhrman, & Barnum, 1995; Butz, Chamberlain, & McCown, 1997; Lichtenberg & Heck, 1986; Pincas, 2001; Tschacher, Scheier, & Grawe, 1998). Lichtenberg and Heck examined the "Gloria" psychotherapy tapes and compared the results of Shannon's entropy measure, Markov chain analysis, and sequential analysis. Each of these approaches showed some merit and each had associated limitations. In terms of therapeutic process and outcome, two therapy studies have applied Shannon's entropy measure with somewhat contradictory results; one found that, over the course of intervention, verbal utterances became increasingly complex (Badalamenti & Langs, 1992), and the other found that client and therapist measures of therapy sessions became increasingly coherent (i.e., less complex, according to the entropy measure) and that this tendency was related to treatment success (Tschacher et al., 1998).

Finally, a study conducted by Pincas (2001) recently set out to demonstrate that when treatment works, therapy sessions become both more complex and more coherent. This preliminary study may be particularly relevant to

developmental psychopathologists because it was based on assumptions from family systems theory (Minuchin, 1974). Pincas was interested in empirically testing one of the basic assumptions of family systems therapy: that families maintain a state of equilibrium through negative feedback processes that dampen deviations. These deviations (e.g., depressive withdrawal, angry outbursts) manifest as symptoms for a particular family member but also serve to maintain homeostasis in the family (e.g., Minuchin, 1974; Minuchin & Fishman, 1974). For example, a child may become oppositional in order to (consciously or unconsciously) distract the family from the “real” problem: intense marital discord. When the child acts out, the parents join forces and attend to the disruptive behavior, which precludes escalation of the marital conflict (dampening process); thus, the family maintains a state of equilibrium, however dysfunctional it may be. The goal of family therapy is twofold: “to disrupt or block these negative feedback processes, promoting family disequilibrium and reorganization” and to “capitalize on natural deviation-amplifying processes within family systems in order to bring about systemic change” (positive feedback; Pincas, 2001, p. 145). In short, the goal of therapy is to induce a phase transition in the family system.

As a first step toward validating these assumptions, Pincas conducted a pilot study in which he analyzed the conversations of one family undergoing therapy. He used an analytic technique called *orbital decomposition* (OD; Guastello, Hyde, & Odak, 1998), which combines Shannon’s entropy measure and measures of Lyapunov dimensionality, as well as others, to identify hierarchical patterns, the extent of randomness in a time series, and the optimal level of analysis for any particular series (i.e., the number of units in a string that best captures the information for a time series). The results confirmed that, indeed, the family exhibited evidence of both coherence and complexity across treatment sessions. Because this was a pilot study, we are hesitant to make too much of these findings. But OD may hold particular promise for developmental psychopathologists because it was developed for analyzing *categorical* time-series data, instead of the usual continuous series. As such, it addresses a major limitation that has been repeatedly raised with the other time-series techniques reviewed here.

The use of the entropy measure has only begun to be explored in clinical research. Some of the kinds of questions that can be explored with this measure include the following: Do families at the beginning of a particular intervention exhibit interactions that are highly stable and predictable (i.e., low entropy)? Does the entropy index change over the course

of treatment as old rigid patterns of interaction disintegrate and new ones get the chance to emerge? Does successful treatment necessarily show this kind of rise in unpredictability profile across sessions? Do families restabilize in new patterns at the end of treatment, as indicated by a fall-back to a relatively low entropy score? In other words, can effective treatment be characterized by a developmental phase transition?

The methods for analyzing nonlinear dynamics described in this section have been applied to single-time series. These are appropriate for some biological measures with high temporal resolution (e.g., heart rate), but another form of continuous data, electrical activity in the brain, presents a more complex challenge. There are increasingly more developmental psychopathologists who are integrating brain activity measures in their research programs (e.g., Calkins & Fox, 2002; Cicchetti & Dawson, 2002b; Nelson et al., 2002). Although there is clearly not enough space to discuss the various brain imaging methods in the current review, a word on these techniques is warranted. Ongoing electrical activity in the brain, measured by electroencephalogram (EEG), can involve as many as 256 separate time series, one per electrode. Methods that analyze these kinds of complex data are designed to find relations and patterns among and across these various time series. For example, developmental neuroscientists interested in the self-organization of brain dynamics have found real-time synchronization across distal cortical areas to be correlated with attentional states or focused perception (Lewis, 2005). Transient, organized activity in different regions oscillating in phase (“phase synchrony”) and cortical “coherence” (a similar measure that incorporates both amplitude and phase) are detected through various temporal correlation methods and have been found to correspond with attentional (e.g., Engel, Fries, & Singer, 2001) and emotional (Paré & Collins, 2000) events.

We close this section with a cautionary note that applies to any dynamical mathematical technique. Because these techniques are derived from other fields, often it may be easier to input numbers into the equations than to sensibly interpret the results of the computations. A number of DS researchers have been criticized for interpreting their mathematical functions too literally; either the data inserted into the equations do not conform to the mathematical assumptions or, perhaps more serious, the data are potentially arbitrary in terms of their psychological meaning. These methods hold a great deal of promise, but there also remains a great deal of theoretical and empirical work before the psychological meaning of nonlinear dynamic techniques is clearly understood.

Developmental Time Measures

In the following section, methods appropriate for the study of developmental phenomena are described. Like the real-time techniques, some of these methodologies have been specifically designed to test DS-based hypotheses, while others seem to us particularly commensurate with this aim.

Descriptive Developmental Profile Analysis

The empirical work by Thelen and colleagues (e.g., Thelen & Smith, 1994; Thelen & Ulrich, 1991) has been characterized as descriptive in that it is nonparametric, uses descriptive statistics, and often relies heavily on displaying individual developmental profiles graphically. These researchers most often collect continuous time-series data (e.g., in toddlers learning to walk, the number of alternating steps, degree of displacement of foot, proportion of stepping cycle) over repeated occasions across a significant developmental period. They create developmental profiles on a case-by-case basis and describe the similarities and differences among these profiles. A core concern in this type of analysis is to identify periods of transition during which variability dramatically increases and old behavioral habits dissolve, giving rise to new ones (e.g., from crawling to walking).

The most straightforward way to graph developmental growth profiles is to simply plot scores for the collective variable (e.g., alternate stepping) on the *y* axis across several developmental time points on the *x* axis, and to do so for each case individually. Van Geert and van Dijk (2002) offer a number of additional methods for visualizing and describing intraindividual time-series data over repeated observations. These methods were specifically created for measuring changes in variability across developmental time, and they are well-suited for one-dimensional continuous longitudinal data. In addition, with any individual developmental profile plot, several trajectories can be grouped into clusters that show similar profiles by using variations of a cluster analytic procedure (e.g., Hollenstein et al., 2004).

One simple but elegant plotting technique is referred to as the *moving min-max graph* (van Geert & van Dijk, 2002). This graph represents the developmental trend line, but also the variability around this trend line in a bandwidth of observed scores. A moving window is used; that is, a time frame that is selected by the researcher (e.g., 2 weeks, 3 months) is moved over one position all the way across the time series such that each window partly overlaps with the previous window. There is no absolute window length that is required, but van Geert and van Dijk suggest that the window size should be about one-tenth the

size of the entire data set and no less than five data points. The maximum and minimum score at each time window is plotted, and then the bandwidth of these scores can be examined in terms of its stability and change. In addition, a moving average that corresponds to the moving min-max window can be computed and displayed along the middle of the bandwidth. Figure 22.10 shows a graph taken from van Geert and van Dijk's study in which they showed the developmental trend for one child's acquisition of spatial prepositions. They used a time window of 18 days across a 10-month period. The graph shows that there is a moderate size bandwidth in the beginning of the trajectory and then, after a couple of oscillations, a large increase in the bandwidth, which is maintained until the end of the observation period. The authors interpreted this plot as suggesting a developmental transition (one that showed the characteristics of a phase transition) in the use of spatial prepositions. For a more detailed examination of the values in the bandwidth, the authors also propose using an "altitude line graph," which simply depicts intermediate values as well (e.g., the second highest and second lowest values, percentiles), with a line connecting these values. The result is a plot that resembles the contour lines in a geographical relief map. A number of other variations of these variability charts can be found in van Geert and van Dijk.

To explore developmental trends in individual or group data, developmentalists commonly plot idealized or "processed" estimations of a data series (e.g., regression models, smoothing techniques) that obscure information on

Figure 22.10 Moving min-max graph representing one child's acquisition of spatial prepositions (time window of 18 days; last window = 15 days). *Source:* From "Focus on Variability: New Tools to Study Intra-Individual Variability in Developmental Data," by P. van Geert and M. van Dijk, 2002, *Infant Behavior and Development*, 25, pp. 340–370.

variability (this is what they are designed to do: smooth out fluctuations). In general, developmentalists constrain themselves to a very small repertoire of smoothing techniques and, thus, lose potentially critical information about the characteristics of transitions and the idiosyncratic nature of development (van Geert & van Dijk, 2002). Van Geert and van Dijk argue for the application of more sophisticated smoothing models “which follow the actual rise and fall of the data as faithfully as one wishes” (p. 351). They provide alternatives, many of which are options available in commonly used statistical packages, including SPSS. Some of these techniques include spline models and local polynomial regression models, or loess smoothers, which allow researchers to detect fluctuations and nonlinear trends in their data sets (Simonoff, 1996; van Geert & van Dijk, 2002).

To complement the impressions gained from the graphical developmental profiles, DS researchers may use simple statistics such as within-subject measures of variance (e.g., standard deviations) and correlations to track increases in variability across developmental transition points. The well-known standard deviation (SD) measure is sometimes problematic, however, because of its sensitivity to the mean (i.e., if distributions are censored at a low score, the SD tends to increase when the mean increases), making SDs difficult to compare across individual subjects or samples. To address this limitation, another, less common measure of variability can be used: the coefficient of variation (CV; van Geert & van Dijk, 2002). The CV is simply the SD divided by the mean and, although it too has limitations, it can be used as an alternative to the SD.

Skewness is another easily calculated measure that provides a great deal of information about the pattern of variability in a given trajectory (van Geert & van Dijk, 2002). A skewed distribution is one potential indicator of bimodality, one of the catastrophe flags previously mentioned. In DS terms, bimodality can provide information about the extent to which a particular skill has been acquired or a pattern has been consolidated. For example, in the context of acquiring theory of mind (ToM), a 3½-year-old child who is just beginning to understand that others may hold false beliefs about the child will likely show very few correct responses to ToM tests over several weeks of repeated testing; these will show up as positive outliers. In general, the child will still be responding “incorrectly,” as if he or she has no false belief understanding; thus, the distribution will be positively skewed. At the age of 4, however, this child will likely show a negatively skewed distribution of responses; the child’s ToM skills will have consolidated and now only very rarely will the child respond as if he or she did not understand that others can hold false beliefs.

A similar example might be used for thinking about children in treatment. For instance, at first, a child undergoing cognitive-behavioral therapy for problems with anxiety may respond to frightening or challenging situations with predominantly avoidant strategies and very few proactive, assertive behaviors (i.e., the distribution will be positively skewed, with most behaviors falling toward the avoidant end of the continuum and a few outliers falling toward the assertive end). But if treatment is successful, this child may end therapy showing a pattern of responses that is negatively skewed. The point at which the distribution shifts from being positively to negatively skewed may provide key information about the timing and profile of change across treatment. From a DS perspective, it is likely that this child’s distribution of avoidant-assertive scores from pre- to posttreatment will shift from positively skewed to bimodal to negatively skewed; that is, at no point will the child exhibit responses that show a normal distribution. This pattern would suggest an abrupt shift (a phase transition) in response styles that may be related to treatment success. The main point here is that instead of trying to “normalize” distributions at any stage, information about skewness and variability can provide insights about the nature of transitions and developmental change.

Standard statistical packages (e.g., SPSS, SAS) provide tests for assessing skewness. A Kolmogorov-Smirnov test provides a statistic for sample sizes (or number of observations) greater than 50, and the Shapiro-Wild test for sample sizes less than 50 (van Geert & van Dijk, 2002). In addition, van Geert and van Dijk describe bootstrapping methods that provide researchers a “random sample” with which to compare statistically significant differences in skewness values across a given developmental trajectory.

Finally, individual growth curve modeling procedures can be applied to examine different profiles of change on both the individual and group level. This method is familiar to many developmentalists; it has been applied to examine different trajectories of antisocial behavior (e.g., Nagin & Tremblay, 1999), infant vocal development (Hsu & Fogel, 2001), and infant-mother interactions (van den Boom & Hoeksma, 1994), as well as many other domains. Several easily accessible computer programs are available to run these modeling procedures, including multilevel analysis and hierarchical linear modeling.

Latent Class Analysis

Descriptive developmental profile analyses, as we have described them, are generally restricted to continuous one-dimensional data. Categorical and nominal data are difficult to use with these approaches (without somehow trans-

forming them into continuous data). In this regard, combining different types of developmental profile analyses with methods that can capture content-specific changes in categorical or ordinal variables may be important. Another elegant option for investigating the bimodal properties of a distribution is offered by van der Maas (1998): latent class analysis (LCA). This technique is appropriate for analyzing categorical data. A number of developmental psychopathologists familiar with modeling procedures such as structural equation modeling (SEM) and hierarchical linear modeling (HLM) may also be aware of this method. LCA is conceptually similar to cluster analytic procedures in that it identifies subgroups or types. But it has additional power because it also provides a maximum likelihood estimation and is adaptable to different data structures with no a priori assumptions about the distributions.

As a cognitive developmentalist, van der Maas (1998) is particularly interested in this method for modeling the bimodal response distributions identified on various cognitive tasks at developmental transition points or across various contexts. He argues that cognitive strategies can be best understood as attractors that are more or less available at different ages and in different contexts. In his approach, response patterns to multiple tasks are analyzed in terms of a cusp-catastrophe model, and multistable states (bimodality) are identified through LCA procedures. By presenting several examples of the application of rule and strategy detection in multiple domains, van der Maas showed that LCA may be one of the more promising psychometric models for identifying attractors and multistable states with categorical data.

Dynamic Growth Modeling

A group of scholars from the Netherlands can be credited for having pioneered the use of dynamic growth models in the study of cognitive developmental transitions (e.g., van der Maas, 1998; van der Maas & Molenaar, 1992; van Geert, 1994, 1995, 1997a). The class of techniques advocated by these researchers is often grouped under the heading *nonlinear dynamics*, in reference to the modeling techniques and equations that are associated with this branch of mathematics. Although the techniques have often been applied to real-time data, these scholars explore various applications to developmental modeling instead.

Dynamic growth modeling was developed to simulate change over time (or growth) using logistic difference equations. Van Geert (1994) has used this procedure to model the processes underlying stage-like transitions in the growth of syntactic forms. The basic DS premise of van Geert's technique is that development of cognitive capaci-

ties is much like the self-organized proliferation of multiple species over the course of evolution. Van Geert models cognitive "growers" that constitute a complex system of intraindividual and environmental relations. Like the real-time coupled equations described earlier in reference to Gottman's work, the modeling procedure is realized with iterative equations in which behavioral states are updated by the amplifying and dampening forces inherent in the system's (i.e., the child's) experiential history combined with current external (contextual) resources and limitations. The growth models depict the kinds of nonlinear developmental profiles predicted by stage theorists (e.g., Piaget and Vygotsky). They also emphasize the use of graphical procedures to plot empirical data from longitudinal studies of children's cognitive skill acquisition to match these empirical profiles to the data from simulations derived from the equations. The mathematical formulations used in these models are common in other disciplines; what makes these models unique is the application of both psychological and DS concepts to identify the mechanisms of growth in observed developmental profiles. Another critical strength of this approach is that the process of developing simulations forces the researcher to specify the null hypothesis explicitly. The conventional a priori comparison between the hypothesized result and a lack of any effect is replaced by a specific null hypothesis of an alternative pattern of results.

Recently, van Geert and his colleagues (Steenbeek & van Geert, in press) have broadened their cognitive developmental focus and have become interested in modeling children's peer play interactions. This new modeling endeavor may be more relevant to developmental psychopathologists because of its content (i.e., peer interactions), but more important, it may prove more generalizable to a large body of social interaction problems that developmental psychopathologists are interested in tackling.

Similar to previous endeavors, the procedure begins with a theoretical model. In this case, Steenbeek and van Geert (in press) developed a theoretical model that stipulated that differences in peer interactions with rejected versus popular children can be understood as a function of the following reciprocally interacting factors: each child's goals (autonomy and involvement), the drive that results from the extent to which these goals are met, the emotional appraisal at each given moment, and the resulting emotional expression and behavior. These theoretical factors are then formalized into a mathematical model that stipulates the mechanism differentiating rejected and popular children's dyadic interactions. Because this is a DS-based model, the mathematical formulation necessarily includes

reciprocal, iterative processes and feedback cycles within and across occasions, as well as sensitivity to random or chance variations and the potential for nonlinear results. Next, the simulation is run repeatedly, and the results of the simulation are compared to theoretical expectations. Finally, the results of the simulation are compared to empirical data from real dyadic interactions.

The model includes a number of input parameters that can be set at the outset. These values can be start values for a particular variable or the strength of the connection between two variables. Rejected and popular children, for example, are assigned different preference values according to the original theoretical model. Figure 22.11 is a representation of the simulation model with all of the reciprocal and iterative processes depicted by arrows. Table 22.3 shows the different parameters and what values can be manipulated at the outset. The table also shows the parameter profiles for each type of dyad (the various combinations with rejected, popular, and average children). The model is run, for example, 1,000 times with the particular inputs specified in Table 22.3 for children with different sociometric status.

One of the unexpected results that emerged from running the simulations was that, contrary to what previous literature suggested, the data representing rejected children playing with normal-status children showed more positive emotional expressions than that for popular children with normal-status children (Steenbeek & van Geert, *in press*). When these simulation results were compared to actual

empirical data, the results matched (statistical tests described by the authors in detail were run to compare the simulated and empirical results). The authors concluded that, because rejected children seldom had a chance to play with other children in general, the new experience of playing with someone else led to the expression of more happy emotions than expected. The popular children, on the other hand, were not as pleased with the experience because they were not playing with their regular friends and had plenty of opportunities to play with other children.

The authors suggest that the modeling results are consistent with contextualist, functionalist, and dynamic systems perspectives. Indeed, their models remain true to fundamental DS assumptions. Broadly, the simulation technique demonstrated that emotions and behavior

[are not a function of] personality characteristics that are relatively independent of the contexts and of the local and temporal realization of the concerns. . . . [Instead, the findings] emphasize the importance of iterative and interacting processes that take place in real time. It overthrows the classical distinction between independent and dependent variables in favor of a process of mutually interacting and simultaneous processes. (Steenbeek & van Geert, *in press*)

Van Geert (1998c) emphasizes the critical role mathematical modeling plays in developmental research: "In order to find out the implications of theories, they have to be transformed into mathematical models that capture the

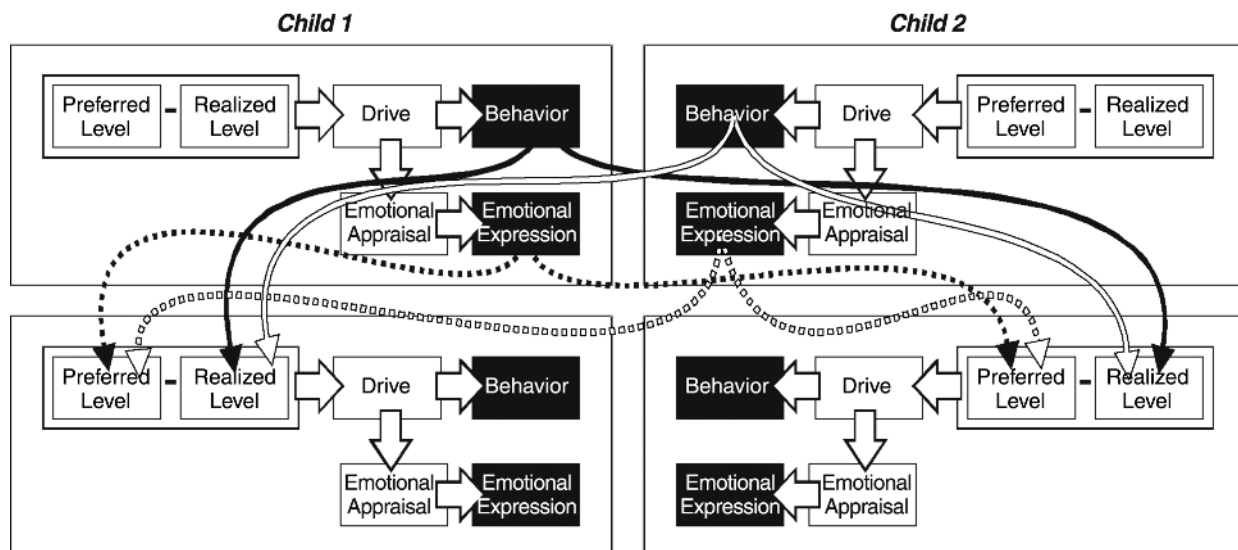

Figure 22.11 Steenbeek and van Geert's (*in press*) peer interaction simulation model. The first row of boxes represents the first moment in time, t ; the second row represents the second moment, $t+1$. Thin arrows represent the iterative feedback components (the output of one iteration is the input for the next).

major dynamic principles of such models and that can be used to explore the range of developmental trajectories under all possible or likely parameter conditions” (p. 155; also see Newton, 1994; van Geert, 1994). But despite van Geert’s concerted efforts to make his approach accessible, its impact on developmental psychology and developmental psychopathology may be limited because of its use of mathematical procedures that are daunting to most psychologists. More important, a great deal of the developmental phenomena that researchers are interested in examining are not conducive to this sort of modeling because they are not easily quantified as continuous variables. Also, regardless of the domain in which this method is applied, and as with all simulation techniques, the correspondence of the parameters in the model with genuine psychological mechanisms is often difficult to evaluate and runs the risk of seeming “arbitrary.” Nevertheless, this modeling technique and others may prove useful for developmental psychopathologists who have very precise hypotheses that can be faithfully translated into mathematical functions that specify mechanisms of change, influence, and interaction.

Connectionist Modeling

Connectionist and dynamic systems theories have separate histories but share a great many commonalities (Spencer & Thelen, in press). Although it is not quite accurate to characterize connectionism as a dynamic systems methodology, we would be missing an important contribution if we were not to include this modeling approach. Many (but not all) connectionist models are indeed dynamic systems, and researchers working with these models often turn to concepts such as attractors, bifurcations, and chaos to understand their properties (Smith & Samuelson, in press).

Connectionism is often characterized as a framework for simulating idealized brain-like, or “neural network,” processing. This is because connectionist modeling starts with the propagation of activation across a network of abstract units that can be hypothetically likened to networks of neurons that fire or do not, depending on the context. Knowledge, representation, or meaning is understood as being “stored” not in one or two units, but in connection weights between processing units. Learning and development is evidenced by changes in connections between these units. These changes result from statistical regularities in the input to the network, and these regularities are governed by the Hebbian learning principle: Units that fire together, wire together. Thus, “the connection weights between layers [of units]—the response of the network to a specific input—depend on the statistical regularities in the network’s *history* of experiences” (Thelen & Smith, 1998, p. 580). Through their own real-time activity, without any additional intervention, connectionist networks change their own connections and, thus, “teach” themselves. One of the best-known examples of a connectionist model is Rumelhart and McClelland’s (1986) demonstration of a network that acquired irregular and regular forms of past tense and overgeneralized (as real children were thought to do) the irregular forms. Their breakthrough was to show that a network could behave as if it was governed by higher-order rules with no such rules having been prespecified.

In most connectionist models, activation among units is a continuous temporal process. Differential equations are used to simulate this continuous activation process such that weighted connections link the rate of change in one variable to the inputs received from the other units (e.g., Munakata & McClelland, in press). In many recent models, the activation process is assumed to be nonlinear. A simple

example is provided by a nonlinear adjustment to McClelland's (1979) cascade model:

$$\frac{dneta_i}{dt} = k_j \left(\sum a_j w_{ij} - a_i \right)$$

$$a_i = f(\text{net}_i)$$

where a represents the activation of receiving unit i , a_j is the activation of sending unit j , w_{ij} represents the connection weight from unit j to unit i , and k is a time constant that sets the rate of change. Neta_i refers to the net input to unit i , and f is a nonlinear function (Munakata & McClelland, in press).

In terms of development, connectionist simulations based on variations of the nonlinear differential equation have been developed to understand category and word learning (Plunkett, 1993; Smith, 1993, 1995), children's knowledge of dimension words and their selective attention to each dimension (Gasser & Smith, 1996; Smith, 1993), the development of face recognition (Johnson & Morton, 1991), and the "A-not-B error" (Munakata, 1998), among others. In terms of the A-not-B error, Thelen and colleagues (Smith & Thelen, in press; Thelen, Schoener, Scheier, & Smith, 2001) extended past connectionist models by applying the dynamic systems principles of multicausality and nested time scales and developed a "dynamic field" model. They incorporated the idea that instabilities in network activities (i.e., variability) index qualitative changes in systemic behavior. Spencer and Schoener (in press) summarize this dynamic connectionist model: "Instabilities disrupt the one-to-one input-output mapping and make dynamic fields nonstandard neural networks."

Connectionist modeling, like other dynamical modeling techniques we have described, requires either a great deal of technical expertise or collaboration among researchers with various talents (e.g., computer programming, mathematics, developmental theory). We are aware of very few efforts in developmental psychopathology to apply this type of simulation procedure, but there may be a number of phenomena in the field that could benefit from such an approach. For example, different types of friendship formations on the playground may be modeled through connectionist procedures. Children seem to self-organize into coalitions or cliques very quickly at the beginning of a school year. These emergent groupings may be modeled as networks of units that become strengthened over time. Different types of coalitions (e.g., bullies and victims versus supportive friendship relationships) may exhibit unique

properties (e.g., bullies/victims may be less stable, more perturbable, and less likely to include new members than other types of friendships). These unique properties may suggest adjustments to existing theoretical models of friendship formation and even have the potential to suggest change mechanisms that may be targeted through intervention.

Readers interested in applying connectionist modeling are directed to *Rethinking Innateness: A Connectionist Perspective on Development* (Elman et al., 1996) and the companion book *Exercises in Rethinking Innateness: A Handbook for Connectionist Simulations* (Plunkett & Elman, 1997). These volumes provide a thorough primer in connectionist modeling and give novices an opportunity for hands-on practice. The authors make important distinctions between mechanisms of change and development and the content of those changes. Of special concern is the attempt to understand emergence and nested interactions at multiple time scales. The exercise book is a practical step-by-step manual that includes computer software and several example simulations that model, for example, stagewise development and how children learn the past tense.

Catastrophe Modeling

This is a mathematical procedure wherein several control parameters can be used to account for discontinuous change in one of seven topological forms (catastrophe models; Thom, 1975; cf. Guastello, 1995). As such, it has some appeal for developmental psychopathologists interested in incorporating insights from developmental stage theories or modeling nonlinear changes in behavior due to treatment or trauma. These models show how each of the possible combinations of control parameters results in different values of a dependent variable. The potential values of the dependent variable are represented on a plane, much like a state space. Nonlinear shifts can be depicted as a fold or curl in the plane, showing where behavior changes suddenly rather than continuously.

The simplest and most commonly used catastrophe model is a cusp catastrophe, as depicted in Figure 22.12. The top surface of this three-dimensional figure is the behavior plane, which is made up of all the possible values of the response variable (i.e., collective variable). The location of a point in the behavior plane is predicted by the values of the control parameter and the splitting factor (the axes on the bottom plane, called the control plane), which are equivalent to independent variables in these models. The top left position on the behavior plane (point A), for instance, is a combination of a low value of the control pa-

Figure 22.12 Basic cusp-catastrophe model.

parameter and a low value of the splitting factor. Keeping the splitting factor constant for the moment, follow the movement from point A to point B. Here we see that there is a linear response in behavior as the control parameter increases continuously. However, when the values of the splitting factor are high, there are some values of the control parameter that result in two possible locations on the behavior plane (points D and E or F and G). This cusp fold in the behavior plane is the region that describes the nonlinear response dynamics of the system. As the control parameter increases from the lowest value at point C, the behavior increases through points G and D. However, at point D, the collective variable value suddenly “jumps” to point E on the plane. When the control parameter decreases from its maximum value, behavior passes through point E to point F in a linear response. Now at point F, behavior suddenly “jumps” down to point G, a much lower value for the collective variable. This difference in response, depending on whether the control parameter is increasing or decreasing, is one of the unique features represented by cusp models and exemplifies the process of hysteresis.

For example, consider the relationship between frustration and anger. The first step in catastrophe modeling is to identify that a catastrophe exists. The catastrophe flags mentioned earlier are used for this purpose. Presence of hysteresis, divergence from linear response, sudden jumps, bimodality, anomalous variance, and critical slowing down can all serve as flags. For the current example, suppose that through experimentation a researcher discovers a bimodality in the distribution of anger responses to frustration. In cases where frustration is moderate, anger is either high or low but never in between. This would be an indication that a cusp catastrophe could be an appropriate model. Moreover, suppose that this bimodality occurs only in high-reward

contexts, and that frustration and anger have a positive linear relationship in low-reward contexts. Thus, for this example, anger is the collective variable of interest, frustration is the control parameter, and amount of reward in the context is the splitting factor (Figure 22.13). In a low-reward task (e.g., no motivational incentive other than following instructions), as frustration increases, the anger response would increase gradually (path A to B in Figure 22.13). In a high-reward task (e.g., in a gambling context), as frustration increases, the anger response would break from linearity at point D. Anger would suddenly jump to a higher level at point E. If frustration continues to increase, there would again be a linear increase in anger. However, frustration would have to subside well below the levels at which the previous jump occurred (point F) before anger decreased nonlinearly to its former level.

The next step of the modeling procedure is to fit the model to empirical data, much like linear regressions are fit to data. Catastrophe models have been used to model diverse developmental transitions such as conservation of liquid (van der Maas & Molenaar, 1992), acquisition of syntax (Ruhland & van Geert, 1998), infant reaching with grasping (Wimmers, Savelsbergh, van der Kamp, & Hartelman, 1998), dating (Tesser & Achée, 1994), blame responses of victims of assault (Lanza, 1999), adolescent smoking (Byrne, Mazanov, & Gregson, 2001), alcohol use (Clair, 1998), and anxiety in preuniversity students (Haslett, Smyrniotis, & Osbourne, 1998). These and other examples indicate that, despite the difficulty in specifying or measuring control parameters, as discussed earlier, important insights about the profiles and mechanisms of change can be gained. Catastrophe theory and models will likely become more applicable as more researchers address

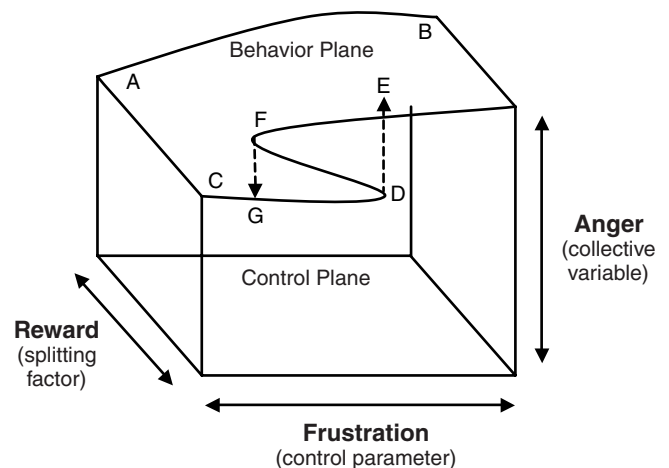

Figure 22.13 Cusp catastrophe model representing the relationship between anger and frustration in different contexts.

the nonlinearities in their data and work to measure hypothesized control parameters.

STATE SPACE GRID ANALYSIS: A GRAPHICAL AND STATISTICAL MIDDLE ROAD

The various DS techniques introduced thus far have considerable potential for addressing some of the analytic challenges faced by developmental psychopathologists. However, we have also pointed out some obstacles for implementing these techniques. In general, most techniques require continuous data, whereas ordinal and categorical variables are more common in developmental psychopathology, especially in observational studies. In addition, many of the techniques are either solely descriptive, preventing researchers from testing the strength and reliability of their findings, or they require complex mathematical procedures that may be inaccessible or irrelevant to most developmental psychopathologists. Recently, a middle ground of hybrid strategies has been developed that combines graphical techniques that capture the descriptive richness of DS concepts with simple statistical procedures that stay true to systems assumptions (Granic, Hollenstein, et al., 2003; Granic & Lamey, 2002; Lewis et al., 1999).

In this section of our review, we introduce this new method, state space grid (SSG) analysis. This technique was developed by Lewis and his colleagues to address some of the limitations in previous DS methods. It is a graphical and statistical strategy that links the analysis of real-time and developmental time patterns and allows for the identification of individual and group differences. Thus, the flexibility of this methodology may prove to be valuable for developmental psychopathologists. We begin by describing the graphical technique and then move on to the various measures that can be derived from these graphs for statistical analysis. Examples of studies in developmental psychology and developmental psychopathology are provided throughout.

State Space Grids

Recall that DS theorists use the concept of a *state space* to represent the range of behavioral habits, or attractors, for a given system. In real time, behavior is conceptualized as moving along a trajectory on this hypothetical landscape, being pulled toward certain attractors and freed from others (see Figure 22.1). Based on these abstract formalizations, Lewis et al. (1999) developed a graphical approach that utilizes observational data and quantifies these data according to two ordinal variables that define the state space for any particular system. Lewis and his colleagues (e.g., Lewis

et al., 1999; Lewis et al., 2004) have primarily studied intraindividual attractor patterns that emerge and change in the early years of life. The grids they originally developed utilized two ordinal variables (e.g., degree of engagement and intensity of distress) that tapped individual infants' socioemotional habits across several developmental epochs.

State space grids (SSGs) have also been developed to represent dyadic behavior (e.g., parent-child interactions, peer relations; Granic & Lamey, 2002; Granic, Hollenstein, et al., 2003). The dyad's trajectory (i.e., the sequence of behavioral states) is plotted as it proceeds in real time on a grid representing all possible behavioral combinations. Much like a scatter plot, one dyad member's (e.g., parent) coded behavior is plotted on the *x* axis and the other member's (e.g., child) behavior is plotted on the *y* axis. What is different, however, is that each *x-y* coordinate represents a moment (e.g., second, event, bin) in time, rather than a case in a group of cases. Two behavior streams are segmented into time points or events, and simultaneous values are plotted. Thus, in dyadic grids, each point on the grid represents a two-event sequence or a simultaneously coded parent-child event (i.e., a dyadic state). A trajectory is drawn through the successive dyadic points in the temporal sequence as they were observed. When the behavior changes, a line is drawn connecting the new point and the previous point. For example, a hypothetical trajectory representing 10 seconds of coded behavior is presented in Figure 22.14. The sequence depicted begins with 2 seconds in negative engagement/negative engagement,¹ 2 seconds in negative engagement/neutral, 3 seconds in neutral/neutral, 1 second in neutral/negative engagement, and 2 seconds in negative engagement/negative engagement. Note that the points are also plotted in sequence along a diagonal such that the first state is plotted in the lower left of the first cell and the final state is plotted in the upper right of the final cell. Plotting the points along the diagonal allows researchers to identify when in the session a behavioral event occurred.

The SSG methodology can tap both the content of interactions (e.g., mutual hostility, permissive parenting) and the structure of these interactions. When we refer to structure, we mean the patterning of behavior, regardless of content, such as the relative flexibility versus rigidity of interaction patterns. With SSGs, we are able to examine whether behavior clusters in very few or many states (i.e., cells) or regions (i.e., a subset of cells) of the state space. We can also track how long the trajectory remains in some cells but not others, and how quickly it returns to particular

¹Note that the labeling of cells follows the *x/y* convention such that the first half of the label is the parent's category and the second half of the label is the child's category.

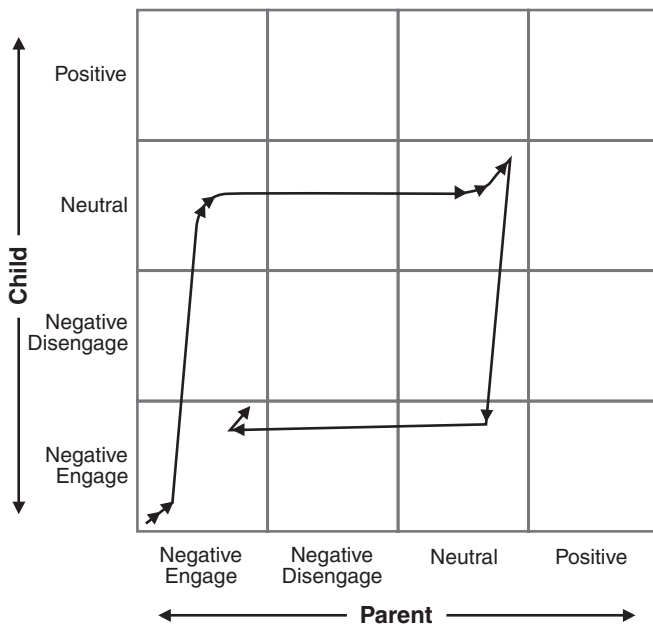

Figure 22.14 Example of a state space grid with a hypothetical trajectory representing 10 seconds of coded behavior, one arrowhead per second. Plotting begins in the lower left part of the cell and moves in a diagonal as each second is plotted, ending in the upper right.

cells. If a dyadic trajectory remains in a small number of cells and makes very few transitions between cells, this system may be thought of as rigid, inflexible, or stuck. In contrast, a trajectory that moves around to many cells in the state space grid and makes frequent changes between these cells may indicate a highly flexible, or variable, system. We can identify attractors as those cells to which behavior is drawn repeatedly, in which it rests over extended periods, and/or to which it returns quickly. Moreover, as discussed in the following sections, a range of variables that capture the relative stability of particular attractors may be derived from SSGs, and these values can be tested statistically for changes in real and developmental time.

A major advantage of SSGs is that they provide an intuitively appealing way to view complex, interactional behavior; thus, they are first and foremost a useful tool for exploratory analysis. A recent study in which we examined the heterogeneity of family interactions with aggressive children may help illustrate this point (Granic & Lamey, 2002). SSGs were used to explore differences in the parent-child interactions of “pure” externalizing children (EXT) and children comorbid (MIXED) for externalizing and internalizing problems. This study is useful not only for demonstrating how the grids work, but also for demonstrating design innovations based on DS principles that are useful with or without SSGs, in this case, a systematic perturbation.

Parents and clinically referred children discussed a problem for 4 minutes and then tried to “wrap up and end on a good note” in response to a signal (the perturbation) within the next 2 minutes. The perturbation was intended to increase the emotional pressure on the dyad, triggering a reorganization of their behavioral system. We hypothesized that, as a function of differences in the underlying structure of their relationships, EXT and MIXED dyads would be differentially sensitive to the perturbation and would reorganize to different parts of the state space. Prior to the perturbation, however, we expected dyads’ interactions to look relatively similar. Separate grids were constructed for the pre- and postperturbation interaction sessions. For this study, the lines (trajectories) are less important to notice than the points that show clustering in particular cells. Figure 22.15 shows an example of an interaction between a pure EXT child and his parent, pre- and post perturbation. As exemplified in these grids, EXT dyads tended to go to the permissive region (child hostile-parent neutral/positive) of the state space grid, as well as other regions (i.e., mutual neutrality and negativity), before the perturbation. After the perturbation, EXT dyads tended to remain and stabilize in the permissive region. Figure 22.16 represents the interaction of a MIXED dyad. Similar to EXT dyads, the MIXED dyads occupied the permissive region, as well as other areas, before the perturbation. But in contrast with the EXT group, MIXED dyads tended to move toward the mutual hostility, or mutual negativity, region of the state space grid after the perturbation. Granic and Lamey (2002) concluded that the perturbation was a critical design innovation that provided the means by which clinical subtypes could be differentiated.

Another contribution of this study was a more general one: The use of SSGs, with their rich case-by-case temporal narratives, provided a technique to further parse interaction processes that have been previously assumed to represent one coherent pattern. In this case, the coercive process (Patterson, 1982; Patterson et al., 1992; Snyder, Edwards, McGraw, Kilgore, & Holton, 1994) was shown to constitute two separate microsocial patterns—two separate attractors on a state space (Granic & Patterson, 2001). Moreover, the conditions under which dyads would be drawn toward one region or the other were found to differ for subtypes. The use of SSGs to uncover heterogeneous processes may be relevant to a variety of phenomena in developmental psychopathology, including variability in the real-time unfolding of attachment patterns (cf. Coleman & Watson, 2000), in bullying interactions on the playground (cf. Pepler, Craig, & O’Connell, 1999), and in parent-adolescent interactions during puberty (Granic, Dishion, et al., 2003; Granic, Holenstein, et al., 2003).

Figure 22.15 Pre- and postperturbation state space grids for an EXT dyad.

State Space Grid Analysis: Real-Time Measures

SSG patterns can be quantified and used as variables for statistical analyses. Variables that capture the temporal and spatial patterning of behavior have been developed for time-based (e.g., second-by-second coding) as well as event-based (e.g., conversational turns) data (Lewis et al., 1999). The

same variables may be used regardless of whether the researcher is using the grids to map individual or dyadic behavioral trajectories. We have provided a list of some of these variables but, depending on the research question, additional ones may be created. Once these parameters have been computed, different types of attractors may be identified and the relative stability of these dynamic states can be

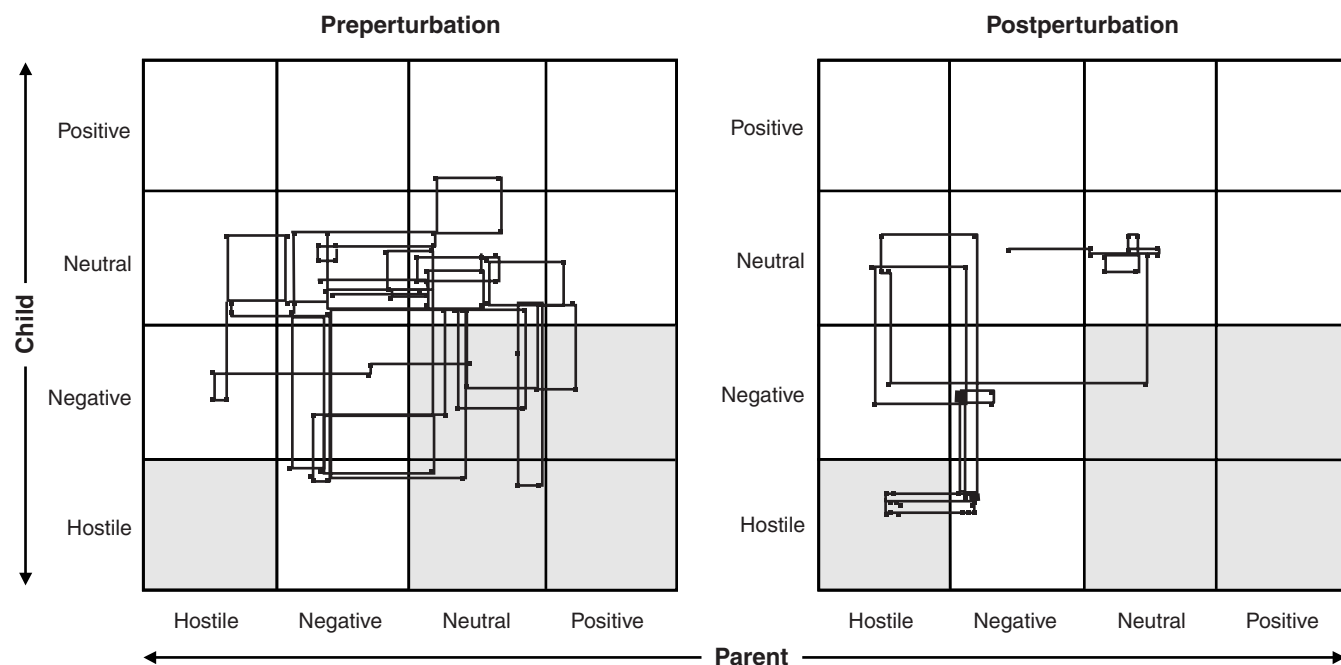

Figure 22.16 Pre- and postperturbation state space grids for a MIXED dyad.

measured and subsequently compared in a variety of ways (Lewis et al., 1999, 2004).

In general, long durations and/or frequent recurrences of behavior in a particular cell or region suggest an attractor on the state space, and these hypothetical attractors can be compared and tested within individuals across development as well as between individuals. Moreover, parameters describing the stability or variability of behavior across the state space can be calculated for each grid, allowing global, structural comparisons over time, populations, or individuals. As we list the parameters that can be derived from the grids, we refer to Figure 22.17 for examples. These grids were taken from a study conducted by Lewis and colleagues (1999) that examined the socioemotional coping patterns of infants and changes in those patterns over a hypothesized stage transition. Originally, these grids were representations of intraindividual behavior plotted according to two ordinal variables, but we have left out the axes labels because they can just as easily represent dyadic behavior, and our intention is to provide a generic description that can be adapted to a variety of observational data. It should also be noted that unlike the grids in the Granic and Lamey study, which used event-based data (conversational turns as observational units), time-based data are plotted in Figure 22.17; larger dots in these plots represent longer durations.

The following are parameters that may be computed for each cell in the grid: (1) raw density: cumulative duration (or number of hits) per cell; (2) proportional density: density divided by total episode duration or total number of events; (3) perseverance 1: mean duration (or mean number of consecutive hits) per cell; (4) perseverance 2: longest duration (or longest series of consecutive hits) per cell; (5) return time: latency to return to a cell following an event in that cell. This can be measured in units of time, number of events, or number of unique cells visited en route. For ex-

ample, in Figure 22.17, grid B shows a high raw density in cells 2/2 (again, cell labels follow the x/y convention) and 2/3 and a very low raw density in cell 1/3. In grid C, cell 3/1 shows a high value for perseverance 1 (each time behavior goes to that cell, and it tends to stay there for some time), whereas cell 1/1 in that same grid shows a low perseverance value. Finally, grid B shows a very low return time for cell 2/2 (every time behavior leaves that cell, and it returns in approximately one turn) but a high return time for grid A, cell 1/0.

There are also several parameters and summary values that can be computed for the entire grid (rather than cell by cell): (1) dispersion: total number of cells visited (with or without controlling for total time or total number of events); (2) fluctuation: number of transitions between cells (with or without controlling for total time or events); note that fluctuation may be high even though dispersion is low, providing an additional useful parameter (see grid B); (3) stability 1: average of either mean or maximum cell duration values (or events per cell) across all cells; note that high values indicate overall stability or stickiness of behavioral states; (4) stability 2: mean return time (in time or event units) across all cells; note that low values indicate overall stability or resilience of behavioral states; (5) peak stability: maximum single duration (in time or event units) out of all the cells occupied. Returning to Figure 22.17, grids A and C show high dispersion, compared to grid B, and grid A shows a low stability 1 value, compared to grid B.

Researchers may choose to calculate one or a few of these whole-grid parameters, depending on what makes most sense in any particular study. Another option is to combine two or more of the whole-grid parameters into one summary construct score or latent variable that represents “flexibility/rigidity” of interaction patterns (e.g., Granic, 2003; Hollenstein et al., 2004). For example, to

Figure 22.17 Examples of three state space grids. *Source:* From “A New Dynamic Systems Method for the Analysis of Early Socioemotional Development,” by M. D. Lewis, A. V. Lamey, and L. Douglas, 1999, *Developmental Science*, 2, pp. 457–475.

create a flexibility/rigidity construct, the SSG parameters of interest are transferred into z-scores and a reliability analysis is conducted to ensure that the chosen parameters are sufficiently correlated and reliably hang together (measured by Cronbach's standardized alphas and Pearson correlations). Any parameters that do not meet appropriate criteria can be dropped, and the z-scores from the remaining reliable parameters can be averaged into one flexibility/rigidity construct score. This potentially more robust score can then be used in any kind of appropriate statistical analysis (e.g., growth curve analyses, SEM, regression analyses, ANOVAs).

In addition to examining the patterns across the entire grid, developmental psychopathologists are often interested in the relative stability of one or just a few behavioral patterns or attractors (e.g., depressed mother-infant mutual gaze, coercive interactions). Lewis and colleagues (1999, in press) have developed a number of quantitative strategies for identifying attractors on a state space grid. Using the measures previously listed (density, perseverance, return time), attractors can be defined as the cell or group of cells highest in these values. Once attractor cells are identified, the computed parameters for those cells serve to characterize the strength, endurance, and stability of the attractor for comparison purposes. These comparisons are particularly powerful when they are conducted across developmental time.

State Space Grid Analysis: Developmental Measures

After computing the parameters that are most relevant for a particular research question, statistical techniques (most of which are quite familiar to developmental psychopathologists) may be applied. We recommend using these statistical procedures in a way that maintains the integrity of the individual (or dyadic) case (e.g., curve estimation procedures, cluster analysis). However, multivariate analyses, including ANOVAs, regressions, and SEM, can just as easily be run on the grid variables.

One example of a developmental state space grid analysis comes from a recently completed study by Lewis et al. (2004). These researchers were examining a developmental transition in late infancy that was hypothesized to exhibit the properties of a phase transition (i.e., increased variability in real-time patterns, a breakdown of old attractors and the emergence of new ones over developmental time). The general hypothesis that guided this study and similar DS-inspired studies that focus on phase transitions is presented in Figure 22.18. Infants were videotaped in frustrating situations on 12 monthly visits before, during, and after a hypothesized transition point at 18 to 20 months. SSGs were

constructed for each episode and grid-to-grid differences were compared over age. As predicted, grid-to-grid differences were greater during the transitional period than before or after, indicating a developmental reorganization of behavioral responses to negative emotion. Also, new attractors appeared more frequently during the period of transition than at other ages.

Lewis and colleagues provide two techniques to measure *within-subject* differences among SSGs. The first is called *intergrid distance* score (IDS) and is computed in the following steps. Grid-to-grid Euclidian distance scores yield a global metric of the difference in behavioral landscapes from month to month, based on the sum of squared differences across all cells. For each grid cell, the difference in duration values over two consecutive months is calculated, then squared, and then these values are summed for all cells. Next, the square root of this sum is taken as the distance score between the two grids.

A second developmental analysis they explored was a cluster analysis technique to look at changes over time. The first step is to categorize the grids by entering all grids for all months for every child into a k-means cluster analysis. The most parsimonious cluster solution is chosen (based on preset criteria). The cluster score for each grid is then recorded. Visual inspection of the grids is recommended at this point to ensure that the same cluster scores look alike topographically, having similar duration values for many of the same cells. Developmental continuity would thus be indicated by a sequence of months (2 or more) with the same cluster score, and developmental variability would be indicated by month-to-month change in cluster membership.

Another method of analyzing changes in SSG patterns over developmental time comes from a recent study that examined changes in the structure of family interactions during the early adolescent transition period (Granic, Dishion, et al., 2003; Granic, Hollenstein, et al., 2003). Following Lewis and colleagues' stage transition hypothesis, we examined whether early adolescence (i.e., around puberty; age 13 to 14 for boys) constitutes a phase transition (a period of reorganization) marked by a peak in the variability of family interactions; before and after this period, interactions were expected to be stable (refer to Figure 22.18 for schematic representation of hypothesis). Longitudinal observational data were collected in five waves prior to, during, and after the transition period. We observed 149 parents and boys problem-solving at 9 to 10 years old, and every 2 years thereafter until they were 17 to 18 years old. Based on this data, state space grids were constructed for all families across all waves. An example of a parent-child dyad across five longitudinal waves is shown in Figure

Figure 22.18 Model of a developmental phase transition; developmental phase transitions are periods of fluctuation in developmental time and increased variability in real time.

22.19. Consistent with our hypothesis, this was a characteristic pattern for the sample: The sequence of state space grids showed that behavior became more variable (i.e., occupied more cells and moved around the grid more frequently) at the third wave, when the boys were in early adolescence (age 13 to 14 years old). Before and after this period, dyadic behavior looked more stable and less flexible; fewer cells were occupied and there were fewer changes between cells. Two parameters indexing the variability of

the interactions (fluctuation and stability) were derived from these grids. Repeated measures ANOVAs on these variables revealed a significant quadratic effect. To ensure that these results were not just significant on the group level, but also characterized the majority of families in the sample (and, thus, to be more faithful to systems-oriented, case-based assumptions), the wave at which flexibility peaked (when fluctuation was highest) was recorded. Results revealed that the majority of families showed a

Figure 22.19 Sample state space grids for one dyad across five longitudinal waves. *Source:* “Longitudinal Analysis of Flexibility and Reorganization in Early Adolescence: A Dynamic Systems Study of Family Interactions,” by I. Granic, T. Hollenstein, T. J. Dishion, and G. R. Patterson, 2003, *Developmental Psychology*, 39, pp. 606–617.

significant peak in variability in the middle wave—and hardly any families peaked in the first or last wave.

From these examples, it should be clear that any statistical tool that has been developed to measure growth or change over time can be combined with SSG analysis. The important difference in these variables (compared to questionnaire data, for instance) is that they capture temporal patterns as they unfold over time. The importance of tapping these dynamic processes in terms of explanatory power cannot be overstated, but developmental psychopathologists are also interested in predicting outcomes. Although some systems scholars have argued that prediction should not be a goal for developmental scientists (much as prediction is not a goal for biologists), others in the field still consider it critical.

We recently completed a study in which one of our objectives was to predict antisocial behavior from dynamic systems measures of parent-child interactions. The study combined descriptive developmental profiles, SSG analysis, and more traditional multivariate statistical procedures (Hollenstein et al., 2004). The main goal of this study was to examine the connection between rigidity in parent-child interactions and the early development of antisocial behavior. We began the study by conceptualizing psychopathology as “diminished flexibility and constrictions in the affective, cognitive, and behavioral correlates of adaptational patterns” (Overton & Horowitz, 1991, p. 3). Clinical researchers have long viewed psychopathology as overlearned, automatized cognitive, affective, and behavioral patterns that are impervious to changes in the environment and interfere with an individual’s ability to function socially (e.g., Cicchetti & Cohen, 1995b; Mahoney, 1991). This view of psychopathology as rigidified patterns of interaction has been theoretically extended to the family system (Minuchin, 1974) and coercive family processes specifically (Patterson, 1982), but empirical studies have not explicitly focused on rigid parent-child interactions and the emergence of child psychopathology.

In this study (Hollenstein et al., 2004), high-risk children in kindergarten ($n = 275$) and their parents were observed for 2 hours engaging in a variety of tasks (e.g., playing a game, problem-solving) that were expected to elicit a range of affect for most families. SSGs were constructed from the coded observational data, and several whole-grid measures of rigidity were derived from the grids. A rigidity construct was created, using methods previously described. As hypothesized, results showed that parent- and teacher-reported antisocial behavior, measured concurrently and 18 months later, were positively corre-

lated with rigidity scores. Children rated high on antisocial behavior were significantly more likely to exhibit more rigid parent-child interaction patterns than their non-antisocial counterparts. Regression analyses also indicated that rigidity scores in the fall of kindergarten predicted growth over 18 months in parent-reported antisocial behavior after controlling for concurrent levels.

We recently extended these results by examining the developmental growth profiles in both externalizing and internalizing behavior for this same sample (Hollenstein et al., 2004). As shown in Figure 22.20, children's growth profiles in externalizing behavior across four waves of data collection (over 24 months) showed four distinct types of trajectories: growers, desistors, stable high, and stable low. Figure 22.21 shows the means on the rigidity construct for the four growth trajectory groups. Results indicated that the growers and stable-high groups scored significantly higher on parent-child rigidity scores than the stable-low and desistors groups. This was an exciting finding for us because of the potential diagnostic implications. Returning to Figure 22.20, the growers and desistors began approximately at the same level of antisocial behavior. What distinguished the group of children who became increasingly more antisocial over time from those children who became less so over time was how rigid the parent-child interactions were at the first wave.

Although the SSG method is clearly still in its early stages of development, we are encouraged by its potential. One of the important advantages to this technique is its inherent flexibility. At the very least, it is a visual, exploratory tool to develop and refine hypotheses. At best, this methodology provides a source from which novel, temporal-based, process-level predictors may be tapped and used to strengthen current models of normal and atypical development. Researchers are not limited to using continuous time series, as is the case with many other DS methods. Categorical and ordinal data are also appropriate for this type of analysis. Also, the grids are malleable in that they can represent systemic behavior on the individual as well as dyadic level. In addition to the examples mentioned, changes in peer, romantic couple, and sibling interactions, for example, can easily be tracked using SSGs. In fact, apart from the difficulties in visually representing the data, the variables derived from the grids can be extended past the two dimensions on which we have focused. For instance, triadic family interactions or family interactions with siblings as well as parents can be measured for attractor strengths, fluctuations, and so on. Along similar lines, peer interactions with three or more children on the playground can be analyzed with this strategy.

Another benefit of this approach is the extent to which it remains user-friendly and does not require expertise in mathematical modeling. In addition, we have developed a graphics-based, point-and-click, SSG software program that will output grids, compute all the grid parameters mentioned previously, and conduct statistical analyses on these parameters (real-time and developmental analyses). The SSG program is available from the current authors.

FUTURE DIRECTIONS: IMPLICATIONS FOR CLINICAL RESEARCH

There are no limits to the diverse topics and varied problems that can potentially be addressed with the application of DS methods; listing all of them here would be impossible. In this final section, we have chosen to limit our discussion to the implications for clinical research, an area in which many developmental psychopathologists share an interest. Because DS methods are specifically designed to capture change processes, and because the study of psychopathology often breaks down into the study of individual patterning, one of the most exciting potential applications of SSGs, as well as other DS tools, may be in treatment research.

SSGs may be particularly well-suited for the study of heterogeneous change processes that may underlie treatment progress and outcome. For example, a great deal of research has shown that family-based treatments targeting coercive interactions can decrease levels of aggression in children, but there remains a great deal of variability in treatment outcome and almost no understanding about the mechanisms of change (Kazdin, 2000, 2001, 2002). The state space grid methodology should be able to provide a microsocial, process-level account of how family and peer relationships change over the course of treatment and follow-up. In addition to identifying content-specific changes (e.g., less hostility and more mutual positivity in parent-child interactions), this method has the potential to tap structural changes associated with treatment success. For instance, as a result of treatment, do parent-child dyads move more quickly from a hostile, conflictual interaction into a reparative one? Do they develop several alternative problem-solving strategies that they can maneuver through more flexibly? These same sorts of questions can be applied to treatments with children with anxiety disorders, depression, and so on.

Recently, we have begun a new program of research focusing on clinical questions in the area of childhood

Figure 22.20 Clusters of antisocial trajectories.

aggression using DS principles and methods. We briefly summarize this program of research, including our design and some of our hypotheses, to illustrate how this novel methodological lens may address previously untenable questions. Our hope is that this research framework may be equally applicable to a range of child psychopathologies and treatment modalities.

The two main objectives of our research are to (1) describe and explain the fine-grained changes in parent-child interactions over the course of intervention and (2) study differences in processes of change and stability according to clinical subtypes. To examine how change unfolds over the course of treatment—and to pinpoint the real-time processes underlying such change—a fine-grained, longitudinal design is required, with repeated assessment points between baseline and termination phases of the intervention. Our focus is on real-time interpersonal processes in family interactions. Direct observations of parent-child problem-solving interactions—with an emotional perturbation introduced part-way through the interaction—are collected every other week during the intervention period. These observations are

videotaped and coded for affect and problem-solving content. SSG analysis will be applied to uncover content-specific changes in parent-child interactions, content-free changes in the structure of these interactions, and changes in dyads' sensitivity to the perturbation, all in relation to suc-

Figure 22.21 Means scores on rigidity construct by antisocial trajectory cluster.

cessful treatment outcomes (as measured by standardized clinical instruments). These trajectories will also be compared by gender and clinical subtype to identify distinct change processes associated with these groupings.

Two of the questions and hypotheses that are being examined are the following:

1. When treatment is successful, what changes can be observed in parent-child problem-solving interactions from pre- to posttreatment? In terms of content-specific hypotheses, we go beyond just hypothesizing that dyads will become less negative and more positive. With the help of the grids, more complex, process-level hypotheses can be put forward. For example, we expect that dyads will spend less time in the mutually hostile/coercive region of the state space, but even with duration in that cell held constant, we expect that when exiting this region, dyads will show longer return times to that cell (i.e., coercion will become less “absorbing”). We do expect that they will be more positive and supportive, but this may happen over the course of an interaction (i.e., dyads will end up in that region, even if they start in the more negative region). Thus, the temporally based, multistable nature of family interactions will be assessed. In addition, the structural properties of the dyad are important to measure. In terms of the behavioral repertoire in general, we expect that those youth who benefit from treatment will develop a less rigid, more flexible interaction style. That is, from pre- to posttreatment, dyads with successful outcomes will visit more behavioral states and fluctuate from one state to another more frequently.
2. Is there a characteristic profile of change in parent-child interactions over the course of successful intervention? Based on DS principles, we expect that when treatment is successful, the biweekly longitudinal profile of change will exhibit the properties of a phase transition. That is, parent-child interactions are expected to be initially stable (i.e., similar from week to week) and mutually hostile, to fluctuate markedly some time after treatment begins (i.e., differ considerably from week to week), and then to restabilize, but in more positive patterns of interactions (and still more flexible than at baseline).

With the application of SSGs, and the parameters derived from the grids, it is possible to test our process-specific hypotheses. As mentioned, we expect that those youth who benefit from treatment will not abandon negative behavioral habits but will soften them through the development of a less rigid, more flexible behavioral repertoire.

This approach can specify at what point in the interaction dyads become hostile, how long they maintain hostile exchanges, the ease with which they escape them, the range of alternative patterns available to them, and the tendency to return to hostility. Dispersion, stability, and fluctuation measures can be computed, and changes in any of these parameters can then be tracked over the course of treatment and follow-up to assess the hypothesis of increased behavioral flexibility in relation to successful interventions. Instead of relying on central tendency measures (e.g., means and correlations), this technique maintains the temporal integrity of real-time interactions and, thus, can better capture some of the microsocial processes hypothesized to be most important.

Our two general research questions are applicable to a range of disorders and treatment programs. Also, different domains of behavior and functioning can be tracked. Changes in peer interactions and sibling interactions, group behavior in the playground, and individual behavior in a variety of contexts can be examined in terms of similar types of process-level questions. The main point is that DS techniques can bring us closer to understanding the change process itself, in whatever domain, and this is a critical new direction in clinical research that we have been repeatedly urged to take. As Kazdin (2000) and others have argued, we have more than sufficient evidence about which treatments work; it is time to shift our resources and develop theories about *how* they work and *for whom*. Such theories may be best informed by DS principles and appropriately tested with some of the diverse set of methods we have reviewed in this chapter.

CONCLUSION

From the beginning of its establishment as a discipline, one of the core priorities in developmental psychopathology has been methodological diversity (e.g., Cicchetti & Cohen, 1995b; Cummings et al., 2000; Richters, 1997). One reason for encouraging this analytic pluralism is the recognition of the disparity between systems-based models of developmental psychopathology and the inadequate methodological tools that are available to test them (Richters, 1997). We have argued that DS approaches to development offer research methods that show greater fidelity to the complex, heterogeneous, temporal nature of developmental phenomena. Clearly, no set of analytic methods can address the mismatch of methods and models entirely; thus, we are not arguing for the complete abandonment of well-established techniques. Instead, our purpose in providing a survey of

DS methods is to encourage developmental psychopathologists to begin examining empirically questions that may have previously seemed out of analytic reach.

It has been 20 years since Sroufe and Rutter's (1984) seminal paper formalized the boundaries of developmental psychopathology. Although roots of the developmental psychopathology perspective extend to at least a decade earlier (Achenbach, 1974), Sroufe and Rutter identified several fundamental themes that defined the burgeoning field and continue to shape our scientific agenda today. Foremost in their exposition was a call for improved prediction of psychopathological outcomes through "the study of the origins and course of individual patterns of behavioral maladaptation"

(p. 18). As they noted more recently (Rutter & Sroufe, 2000), this emphasis on prediction of individual differences emerged in large part out of concern that traditional diagnostic classes, although in many cases reliable, were often reified despite limited evidence of construct validity (see also Kendell, 1989). In becoming so reified, descriptive psychiatric syndromes were being mistaken for and used as explanatory constructs, without acknowledgment of how little was known about the etiological substrates of most disorders. By focusing on causal processes implicated in the emergence of individual differences in behavioral adaptation and maladaptation, it was hoped that the complexities of psychopathological development would become more appreciated and further explored.

Developmental psychopathology's focus on individual differences in the emergence of behavioral maladaptation followed from recognition that almost all psychiatric categories reflect etiologically heterogeneous groups. For example, the impulsive behaviors characteristic of

Work on this chapter was supported by Grant R01 MH63699 to Theodore P. Beauchaine from the National Institute of Mental Health and by Graduate Research Fellowship DGE0203031 to Penny Marsh from the National Science Foundation. We express our gratitude to Sheila Crowell for her helpful comments on an earlier draft. Address correspondence to Theodore P. Beauchaine, Department of Psychology, University of Washington, Box 351525, Seattle, WA 98195-1525. E-mail: tbeauch@u.washington.edu.

Attention-Deficit/Hyperactivity Disorder (ADHD) can result from numerous causal pathways, including genetically influenced central dopamine dysfunction (e.g., Swanson & Castellanos, 2002), structural insults to the central nervous system (e.g., Gerring et al., 2000), and in utero exposure to alcohol and other drugs of abuse (e.g., Niccols, 1994). Moreover, each of these vulnerabilities may interact somewhat differently with environmental risk in producing psychopathological outcomes. The term *equifinality* has been reserved by developmental psychopathologists to refer to instances in which multiple etiological pathways lead to an apparently single behavioral syndrome. Reliance on the behavioral symptoms of ADHD as an explanatory construct obscures this etiological heterogeneity and is likely to hamper our efforts to predict the longitudinal course of individuals afflicted with the disorder. As Sroufe and Rutter (1984) astutely noted, prediction and control are the objectives of all scientific disciplines, and improving our ability to predict longitudinal outcomes is essential for more accurate diagnosis, more effective treatment, and ultimately the prevention of debilitating psychiatric conditions (see also Cicchetti & Rogosch, 2002).

The value of considering individual differences in the development of psychopathology toward improving both diagnosis and treatment is probably best exemplified in the literature addressing childhood externalizing disorders. Moffitt's (1993) reformulation of Conduct Disorder (CD) as either adolescent-limited or life-course-persistent revealed that externalizing children and adolescents with topographically similar cross-sectional behavior patterns can be distinguished from one another based on differences in the longitudinal course of their symptoms. Moreover, these distinct symptom trajectories mark differences in genetic liability, treatment response, and long-term prognosis (e.g., Myers, Brown, & Mott, 1995; Taylor, Iacono, & McGue, 2000; Werry, 1997). Revisions to the *Diagnostic and Statistical Manual of Mental Disorders (DSM; American Psychiatric Association, 1994)* specifying early- and late-onset subtypes of CD therefore reflect an improved understanding of the etiological substrates of the disorder. Indeed, etiology-based diagnosis usually marks progression in the evolution of our nosologic system because it results from increased basic knowledge of the ontology of disordered behavior (Beauchaine & Gartner, 2003; Kendell, 1989).

Even when not developmentally focused, efforts to characterize heterogeneous subgroups of externalizing children have led to advances in intervention research, where several moderating effects of individual differences on treatment response have recently been identified. In the Multimodal

Treatment of ADHD study, children with ADHD and both comorbid anxiety and conduct problems fared best when behavioral management was included with medication management in their treatment. In comparison, no benefit of including behavioral management was observed for children with ADHD who did not suffer from comorbid psychopathology (Jensen et al., 2001). Intervention research on child conduct problems has uncovered similar individual difference moderators of treatment outcome. For example, children treated for early-onset conduct problems improve more when their interventions include teacher training in behavioral management practices if they suffer from comorbid ADHD. In contrast, CD children without comorbid ADHD improve at the same rate whether or not teacher training is included in their intervention (Beauchaine, Webster-Stratton, & Reid, in press). Taken together, these findings illustrate how delineating heterogeneous subgroups of children within current psychiatric classes can improve diagnostic accuracy and increase treatment efficacy. Identifying individual differences that predict treatment response among children with behavior disorders has therefore become an explicit priority of child psychopathology researchers (see Brestan & Eyberg, 1998; Owens et al., 2003).

Yet, from a developmental psychopathology perspective, defining heterogeneities among children already diagnosed with psychiatric disorders is not enough. Rather, efforts to design more effective prevention and intervention programs will be maximized only by identifying children at risk for heterogeneous patterns of morbidity *before* they meet criteria for a psychiatric disorder. As we demonstrate in later sections of this chapter, it is already possible to prospectively identify children at considerable risk for a number of severely debilitating conditions, and to reduce such risk with targeted prevention programs. Nevertheless, considerable barriers must be surmounted before the full potential of the developmental psychopathology perspective is realized. First, methodological techniques that can accommodate and identify individual symptom patterns and trajectories must be further developed and put to use by developmental psychopathologists. Conventional data analytic approaches born from the Fisherian statistical tradition are not well suited for characterizing individual patterns of behavior (see Richters, 1997). Rather, such approaches, including the *t*-test, analysis of variance (ANOVA), and many linear regression applications, assess the significance of group differences on outcome variables of interest. Although questions regarding group differences will always be important in psychopathology research, alternative statistical approaches that are often referred to as *person-centered* techniques must become

part of researchers' data analytic armament to fully elucidate the etiological heterogeneity of psychopathological states and outcomes (see also Beauchaine, 2003b; Cicchetti & Rogosch, 1999). Since its inception, developmental psychopathology has been an integrative discipline concerned with unique combinations of biological, psychological, and environmental risk. Unfortunately, our theoretical models have outstripped the availability and use of appropriate data analytic strategies for characterizing the etiological heterogeneity that such integrative theories imply and predict. Our primary objective in writing this chapter is to describe the strengths and limitations of one class of person-centered techniques, often referred to collectively as *taxometrics*.

A second barrier that must be overcome for the full potential of the developmental psychopathology perspective to be realized is the precedence placed on overt behavioral symptoms in defining and validating diagnostic classes. At present, all diagnostic categories in the *DSM-IV-TR* (American Psychiatric Association, 2000) are composed entirely of behavioral markers of latent psychopathology traits. Because these traits cannot be observed directly, psychopathologists have come to rely exclusively on behavioral indicators to infer unobservable compromises in biological and psychological functioning. As we discuss in greater detail later, this is necessary in the early stages of delineating a psychiatric syndrome, yet it actively inhibits specification of the diverse causes of psychopathology in later stages of diagnostic validation. Here again, the problem results from a failure to delineate etiological heterogeneity within psychiatric groups. This problem is best illustrated by difficulties faced among behavior geneticists in identifying candidate genes for major psychiatric disorders. In behavior genetics research on ADHD, for example, groups of probands are typically selected based on *phenotypic* markers, including hyperactive, impulsive, and inattentive behaviors. Searches for candidate genes are then conducted by comparing allelic frequencies among probands with either siblings, parents, or controls, depending on the design of the study. As we noted, however, symptoms of ADHD have been linked to numerous equifinal pathways, including central dopamine dysfunction, in utero exposure to stimulants and alcohol, and insults to the central nervous system. These pathways do not share a common genetic etiology, which necessarily attenuates estimates of genetic association and may preclude the identification of the genetic substrates of certain subtypes of ADHD. Although more recent behavior genetics studies have attempted to purify the ADHD phenotype by screening out children with head injuries and perinatal insults, etiological heterogeneity

may nevertheless explain why findings from genetics studies have often been conflicting, with primarily small risk ratios observed (Swanson & Castellanos, 2002). As Castellanos and Tannock (2002, p. 619) recently noted, "Nearly two decades of unsuccessful efforts in psychiatric genetics have led to the conclusion that symptom-based diagnostic classification systems do not facilitate (and can actively obstruct) mapping between susceptibility genes and behavioral outcomes."

To deal with this problem, several authors have suggested that psychopathologists avoid an exclusive reliance on phenotypic indicators, or readily observable signs and symptoms, when assessing psychopathology and defining psychiatric classes. Rather, more progress toward characterizing etiological heterogeneities within behavioral syndromes is likely to be made by using both phenotypic and *endophenotypic* markers in future research. Gottesman and Gould (2003, p. 636) define endophenotypes as "*measurable components unseen by the unaided eye along the pathway between disease and distal genotype*." In other words, endophenotypes are biological and behavioral markers of latent vulnerabilities for psychopathology that cannot be observed without careful measurement. Endophenotypic markers fall along the causal chain between genotype and phenotype and therefore lie closer to the genetic substrates of psychiatric disorders than does behavior (Lenzenweger, 2004). Figure 23.1 depicts two levels of endophenotypes falling between the genetic substrates of Schizophrenia and the behavioral expression of the disorder. On the far left are candidate genes associated with

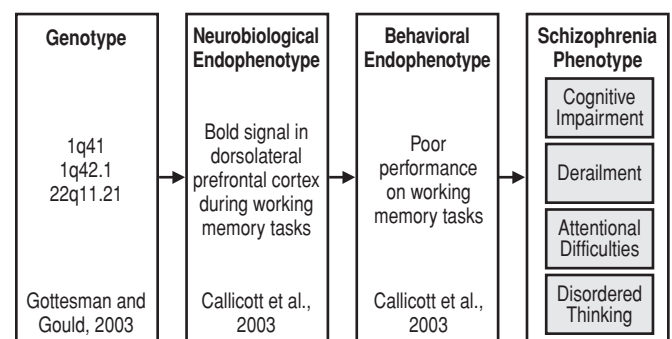

Figure 23.1 Relations among genotypes, endophenotypes, and phenotypes for the example of Schizophrenia. Note that endophenotypes can be identified at multiple levels of analysis including neurobiological and behavioral, and that many additional genetic, endophenotypic, and phenotypic indicators of Schizophrenia have been specified that are not depicted here. *Source:* From "The Endophenotype Concept in Psychiatry: Etymology and Strategic Intentions," by I. I. Gottesman, and T. D. Gould, 2003, *American Journal of Psychiatry*, 160, pp. 636–645.

working memory deficiencies in patients with Schizophrenia. These genes are expressed at multiple endophenotypic levels, including neurobiological and behavioral. At the neurobiological level, both patients with Schizophrenia and their nonaffected siblings exhibit increased blood oxygenation in the right dorsolateral prefrontal cortex during working memory tasks compared with controls (Callicott et al., 2003; Manoach et al., 1999). Thus, both probands and their siblings recruit a broader prefrontal neural network to accomplish such tasks. Notably, however, siblings without the disorder do not exhibit the behavioral endophenotype, poor performance on working memory tasks, nor do they exhibit the phenotypic indicators of Schizophrenia.

This example illustrates several important points about the potential value of endophenotypes in developmental psychopathology research. First, endophenotypic markers that are more proximal to the genetic substrates of Schizophrenia are also more sensitive to shared genetic vulnerabilities than more distant behavioral endophenotypes and phenotypes. Second, carefully chosen endophenotypes often identify latent genetic vulnerabilities *before* full-blown expression of psychiatric disorders, which has major implications for prevention (see also Castellanos & Tannock, 2002; Cornblatt & Malhotra, 2001). Finally, specification of the mechanisms of etiologically heterogeneous psychopathological outcomes will require a focus on latent vulnerability *traits* rather than strictly behavioral syndromes, a view expressed recently by a number of authors (e.g., Krueger et al., 2002; Skuse, 2001) and a point we return to in later sections.

With this discussion in mind, a second objective of writing this chapter is to emphasize the importance of using endophenotypic markers when conducting both psychopathology and developmental psychopathology research. As we will demonstrate, carefully chosen endophenotypes are particularly advantageous when conducting taxometrics studies, both because they are located more proximally to the etiological substrates of psychopathology and because their psychometric properties offer significant advantages over those of strictly behavioral measures (see also Meehl, 1995a, 2001a, 2001b).

In the sections to follow, we first describe the prevailing approach to construct validation in psychiatric research and the problems posed by that approach for identifying etiologically homogeneous diagnostic groups. Next, we outline the potential role that well-designed taxometrics studies could play in improving the construct validation process and the advantages of using taxometric methods compared with other person-centered techniques. Although these sections do not speak to developmental psychopathology specifically,

they are necessary to lay the foundations for the remainder of the chapter. We then provide an overview of commonly used taxometric methods, including recommendations for researchers seeking to perform such analyses. Although other sources of similar descriptions exist (e.g., Beauchaine & Beauchaine, 2002; Lenzenweger, 2004; J. Ruscio & Ruscio, 2004a, 2004b; Schmidt, Kotov, & Joiner, 2004; Waller & Meehl, 1998), our emphasis is on addressing questions of particular concern to developmental psychopathologists, who have been slower to adopt taxometric methods than adult psychopathology researchers (Beauchaine, 2003b). Following this overview, we discuss the implications of using endophenotypes in taxometrics studies for (1) identifying premorbid latent vulnerabilities for psychopathology among at-risk children and (2) targeting children with such vulnerabilities for prevention. Finally, we discuss several additional questions that developmental psychopathologists can address in future taxometrics studies.

CONSTRUCT VALIDATION IN PSYCHIATRIC RESEARCH

As most readers are undoubtedly aware, authors both within and outside the field of developmental psychopathology have criticized the *DSM* on a number of grounds (see, e.g., Hinshaw & Park, 1999; Jensen & Hoagwood, 1997; Richters & Cicchetti, 1993; Winokur, Zimmerman, & Cadoret, 1988). These criticisms include allegations that the *DSM* framework places the locus of disorder within the individual, ignoring contextual information about environmental influences on behavior; assumes biological bases for psychiatric disorders despite claims of being atheoretical and descriptive; lacks developmental guidelines for assessment and diagnosis; fails to capture cultural differences in the manifestations of behavioral maladaptation; is of limited clinical utility because of symptom heterogeneity within diagnostic classes and homogeneity across diagnostic classes; assumes that psychiatric diagnoses are etiologically discrete and categorical; and reduces reliability and statistical power by dichotomizing continuous symptom profiles into categorical diagnoses (Cantwell, 1996; Clark, Watson, & Reynolds, 1995; Cummings, Davies, & Campbell, 2000; Hinshaw, Lahey, & Hart, 1993; Hinshaw & Park, 1999; Jensen & Hoagwood, 1997; MacCallum, Zhang, Preacher, & Rucker, 2002; Sonuga-Barke, 1998; Sroufe, 1997).

Although it is not our objective to review these criticisms in detail, it is noteworthy that to one extent or another, many of them address the inability of *DSM* syndromes to capture heterogeneities in psychopathological

processes and outcomes, raising questions about the *construct validity* of many current diagnostic classes. In psychiatric research, construct validity refers to the extent to which symptoms of a diagnosis mark an objective, nonarbitrary latent entity or attribute, and in doing so discriminate the diagnosis from alternative syndromes. Construct validity must be evaluated whenever the latent cause of a putative trait or disorder cannot be observed directly (Cronbach & Meehl, 1955). Consider the difference between a medical syndrome such as pancreatic cancer, and a common psychiatric condition such as Major Depressive Disorder. In the case of pancreatic cancer, a patient presents at her physician's office with a cluster of symptoms, including nausea, jaundice, abdominal pain, dark urine, and weight loss. This cluster of symptoms enables the treating physician to generate a hypothesis about the etiological substrate of the symptom profile. Of particular importance, this hypothesis is either confirmed or disconfirmed through a biopsy. If the biopsy is negative, a new hypothesis is generated and tested until the pathogen that is responsible for the overt symptoms is identified.

The depressed individual also presents with a cluster of symptoms, including anhedonia, depressed mood, fatigue, weight loss, and insomnia. In contrast to the case of pancreatic cancer, however, there are no pathognomic signs of depression, either biological or behavioral. This leads to somewhat tautological definitions of mental disorders. In the case at hand, the patient is depressed because she presents with a cluster of symptoms, and she presents with a cluster of symptoms because she is depressed; there are no litmus tests to confirm or disconfirm the diagnosis. As Meehl (1995a) noted, behavioral scientists are usually forced to infer latent psychopathological traits using fallible indicators and no gold standard of disease state.

Although often ignored, the difficulties posed for construct validation of psychiatric disorders by the absence of pathognomic signs are quite formidable (Meehl, 1973a, 2004). These difficulties are reflected in the history of the *DSM*, first published by the American Psychiatric Association in 1952. Both the *DSM-I* (American Psychiatric Association, 1952) and the *DSM-II* (American Psychiatric Association, 1968) included symptom lists for major psychiatric disorders that were compiled based on the expert opinions of a small number of primarily psychoanalytically oriented academic psychiatrists. As a result, the diagnostic classes represented in these documents were theoretically rather than empirically based and suffered from poor reliability and validity (see, e.g., Malik & Beutler, 2002). Diagnostic agreement tended to be poor across different clinical and research sites, particularly those representing alternative theoretical orientations. Moreover, almost no evidence

was provided for the validity of most diagnostic categories (Kendell, 1989).

In an effort to address the validity of psychiatric diagnosis, Robins and Guze (1970) published a brief yet influential paper in which they advanced a five-step process toward establishing an objective behavioral syndrome. An extension of Cronbach and Meehl's (1955) construct validation procedure, this five-step approach included clinical description, laboratory studies, delimitation from other disorders, follow-up studies, and family studies. Thus, diagnostic validity is established when a clinical syndrome is characterized by (1) a cluster of covarying symptoms and etiological precursors; (2) reliable physiological, biological, and/or psychological markers; (3) readily definable exclusionary criteria; (4) a predictable course; and (5) increased rates of the same disorder among first-degree relatives. These criteria were applied in the first classification system of mental disorders that emphasized empirically derived diagnostic classes (Feighner et al., 1972). This system, now referred to as the *Feighner criteria*, was adopted by the American Psychiatric Association and has impacted all subsequent versions of the *DSM* (see Cloninger, 1989).

When the Feighner et al. (1972) criteria are met, much greater confidence in the construct validity of a diagnostic class is warranted because more is known about the etiological mechanisms responsible for psychopathology. The rationale behind this conclusion is illustrated in the diagnostic hierarchy presented in Figure 23.2 (Preskorn & Baker, 2002). At the bottom of the hierarchy is *symptomatic* diagnosis, which is purely descriptive. This may include the simple observation that a person appears unhappy, despondent, and hopeless. At the next level is *syn-*

Figure 23.2 Levels of diagnosis. Each move up the hierarchy reflects an increment in knowledge about the causes of a particular diagnostic class. Most psychiatric disorders are specified at the syndromal level.

dromal diagnosis, which follows from the observation that a subgroup of people present with a similar cluster of co-varying symptoms. Here a clinician or group of clinicians may note, for example, that anhedonia, fatigue, irritability, sleep problems, and changes in appetite have been observed across a number of individuals. As noted earlier, all diagnostic classes represented in the *DSM-IV-TR* (American Psychiatric Association, 2000) are syndromal. At the next level of the hierarchy is *pathophysiological* diagnosis. This is possible when the pathophysiology that gives rise to the behavioral syndrome is identified. If appropriate laboratory tests reveal, for example, that the depressive behavioral syndrome is due to hypothyroidism, a pathophysiological diagnosis can be rendered. It is at this level that we begin to understand the process or processes through which the observed symptom profile emerged. *Etiological* diagnosis is at the highest level of the hierarchy. Here, the specific mechanism underlying the symptom pattern is identified. For instance, if antibodies are found that reveal Hashimoto thyroiditis, an autoimmune disease among several pathogenic processes that cause hypothyroidism, then the specific etiology of the depressive syndrome is understood. In general, the development of effective treatments improves as we move up the diagnostic hierarchy because etiological mechanisms can be targeted directly. In the specific case of depression at hand, a strictly syndromal diagnosis would most likely lead to a trial of either cognitive-behavioral therapy or an antidepressant, both of which would be of limited effectiveness because neither targets the etiological substrate of the behavioral syndrome, Hashimoto thyroiditis. The Feighner criteria were published in an effort to move psychiatry away from purely syndromal diagnoses to pathophysiological and etiological diagnoses.¹

¹ In this example, the etiology is clearly biological. It is not our intent, however, to suggest that all etiological agents are disease based. In the case of Posttraumatic Stress Disorder, for example, knowledge of the precipitating traumatic event is essential for a full understanding of any individual case and for effective treatment. Nevertheless, both genetic vulnerabilities and pathophysiological mechanisms are important in the development of the disorder (see Metzger et al., 2004; Orr et al., 2003; Stein, Jang, Taylor, Vernon, & Livesley, 2002). As will become evident in later sections of this chapter, we assume that most psychiatric disorders follow a diathesis-stress model in which biological vulnerabilities are either amplified or attenuated by environmental risk or protection, respectively. Consistent with the Sroufe and Rutter (1984) thesis, the more complex the interplay between biological vulnerability and environmental risk, the more symptom-only-based diagnosis is likely to obscure etiology.

In response to the Robins and Guze (1970) and Feighner et al. (1972) papers, significant effort was expended beginning with the *DSM-III* (American Psychiatric Association, 1980) toward specifying associated features, explicit inclusion and exclusion criteria, the projected course, and the familial pattern of many psychiatric disorders. Nevertheless, nearly 20 years later, most diagnostic categories had not been validated adequately (Kendell, 1989). Although this situation has improved somewhat since the arrival of the *DSM-IV* (American Psychiatric Association, 1994) and *DSM-IV-TR* (American Psychiatric Association, 2000), considerable validation work remains for many if not most psychiatric disorders. Moreover, a number of critics have noted that the expansive proliferation of diagnostic categories in each subsequent version of the *DSM*, from 106 in 1952 (*DSM-I*) to 365 in 1994 (*DSM-IV*), far outstrips observed advances in scientific understanding of both the construct validities and etiological substrates of the additional disorders (Houts, 2002).

An Overreliance on Symptoms

Adoption of the Feighner et al. (1972) criteria as a prototype for construct validation of diagnostic classes is viewed by many as a watershed event in psychiatry that precipitated the rejection of subjectively defined behavioral syndromes in favor of an empirically based, scientifically rigorous nosology of mental disorders (e.g., Spitzer, 1997). How, then, are we in the position just outlined, in which evidence for the validity of most diagnostic classes remains somewhat limited? As we will demonstrate, an overreliance on behavioral symptoms as gold standards in psychiatric diagnosis has impeded specification of heterogeneities in the etiological underpinnings of most disorders. Furthermore, even when endophenotypic markers with the potential to identify etiologically homogeneous groups are identified, they are often eschewed for diagnostic purposes in favor of strictly behavioral criteria. This practice can have serious consequences for our ability to predict the longitudinal course of individuals afflicted with psychiatric disorders, and therefore has significant implications for developmental psychopathologists. Nowhere is this more apparent than in the case of Major Depression.

As we have noted elsewhere (Beauchaine, 2003b), some cases of depression appear to be influenced more by environmental risk, whereas others appear to be influenced more by biological risk (see also Cicchetti & Rogosch, 2002; Harrington, Rutter, & Fombonne, 1996). Although these depression subtypes cannot be readily differentiated based on the behavioral criteria outlined in the *DSM-IV-TR*, evidence

suggests that the dexamethasone suppression test (DST), an indicator of hypothalamic-pituitary-adrenal (HPA) axis reactivity, can identify a subgroup of depressed patients who are at particularly high biological risk for mood disturbance and who are especially prone to later suicide. The DST involves administration of dexamethasone, a synthetic corticosteroid, which normally suppresses cortisol production by the HPA axis. In cases of HPA axis hyperactivity, however, cortisol production is not suppressed. In a long-term follow-up study of 78 depressed patients who were administered the DST, Coryell and Schlessler (2001) found that suppressors had a 15-year suicide risk of 2.9%, whereas non-suppressors had a 15-year suicide risk of 26.8%. Thus, DST nonsuppression offered an *order of magnitude* improvement in the prediction of an extremely important clinical outcome. Moreover, no behavioral indicator performed better than chance in predicting eventual suicide. Yet, by combining behavioral (mood disorder) and biological (DST) criteria, an approach long advocated by some (e.g., Akiskal, 1978; van Praag, 1990), and a suicide risk of greater than 1 in 4 was identified. Furthermore, recent evidence suggests that disturbances in cortisol reactivity may mark liability for melancholic depression among children as young as ages 3 to 5, providing for very early identification of risk (Luby et al., 2003; Luby, Mrakotsky, Heffelfinger, Brown, & Spitznagel, 2004). Given these findings, it is instructive to consider that in the early 1980s, the DST was hailed by many as a promising biological marker of endogenous depression but was abandoned because it did not correspond well enough with the behavioral syndrome. For example, after reporting a sensitivity rate of 55.5% and a specificity rate of 74.5% for the DST in predicting Major Depression, Casat and Powell (1988) concluded that clinical symptoms were more useful than the DST, a conclusion also reached by other authors (e.g., Lu, Ho, Huang, & Lin, 1988). Thus, a heterogeneous behavioral syndrome was used as the gold standard against which the validity of the DST was judged, and an opportunity to refine our diagnostic system in a manner that would allow for better longitudinal prediction of outcome was lost. We now know from family and twin studies that HPA axis activity is roughly 60% heritable (Bartels, de Geus, Kirschbaum, Sluyter, & Boomsma, 2004; Bartels, Van den Berg, Sluyter, Boomsma, & de Geus, 2003) and that polymorphisms in the glucocorticoid receptor gene are associated with some cases of DST nonsuppression (Ruiz et al., 2001). Glucocorticoid receptor gene polymorphisms may therefore mark a homogeneous subgroup within the depressive phenotype who have an especially virulent form of the disorder (see Figure 23.3), a conjecture that will be confirmed or disconfirmed by future research. This is but one

Figure 23.3 Venn diagram depicting heterogeneity (i.e., equifinality) in the depressive phenotype. All three subtypes are captured by the behavioral criteria for depression, but endophenotypic markers are required to subdivide the group into homogeneous subsets.

example of the advantages of conducting assessments at multiple levels of analysis, including both behavioral and biological, toward improving our ability to specify the longitudinal course of psychopathology (see also Cicchetti & Dawson, 2002) and identify premorbid risk.

THE IMPORTANCE OF IDENTIFYING DISCRETE LATENT CLASSES

To this point in this chapter, we have emphasized the significance of using endophenotypes to identify homogeneous diagnostic groups and the implications of doing so for construct validation and for developmental psychopathology models of adjustment. We now turn our attention to approaches identifying discrete latent classes of individuals who are either at risk for developing psychopathology or are already afflicted by psychopathology.

Although most psychopathological vulnerability traits probably are dimensional in nature (D. N. Klein & Riso, 1993), identifying those that are discrete is important because it allows us to draw objective diagnostic boundaries, to identify more homogeneous diagnostic subgroups, and to more accurately predict the long-term course of those afflicted with psychopathology (Beauchaine, 2003b; Beauchaine & Waters, 2003; Meehl, 1995a). For these reasons and others to be outlined, strong evidence for the construct validity of a disorder is provided when members of the diagnostic group comprise a discrete class (Meehl, 1995a). Moreover, when evidence of discrete latent structure is obtained using both endophenotypic markers and

psychological symptoms, the first three of the Feighner et al. (1972) criteria are largely met (Beauchaine & Beauchaine, 2002).

Searching for Boundaries

Despite the advantages of identifying discretely distributed traits, it can be exceedingly difficult to determine whether a distribution of scores on a measured attribute marks a single continuous dimension or an admixture of two or more discrete groups (see Beauchaine & Beauchaine, 2002; Meehl, 1995a; J. Ruscio & Ruscio, 2004a). This is because discrete distributions, when present, are likely to overlap substantially due to both within-group variability and measurement error, rendering most statistical approaches ineffective in detecting multimodal latent structure (Beauchaine, 2003b). Nevertheless, a number of largely ineffective strategies for identifying discrete traits continue to appear in the psychology and psychiatry literatures. We consider several of these in turn.

Bimodality

Perhaps the oldest and least powerful means of identifying discrete subgroups of individuals is to plot the univariate distributions of measured traits or symptoms and inspect those distributions for bimodality. If a bimodal distribution is consistently found across samples, a diagnostic boundary can be inferred at the point of rarity between the two modes (Kendell, 1989). Unfortunately, two discrete distributions usually appear to be unimodal when mixed, even at quite large effect sizes (Grayson, 1987; Murphy, 1964; Waller & Meehl, 1998). The top panel of Figure 23.4 illustrates this for distributions of equal size that are separated by 2.0 within-group standard deviation units. Recall that Cohen (1988) defined 0.8 standard deviation units of separation between group means as a large effect in psychological research. Although the effect size illustrated in the top panel of Figure 23.4 is $2\frac{1}{2}$ times the size of Cohen's definition of a large effect, no evidence of bimodality appears in the admixed distribution. This state of affairs is exacerbated when the mixed distributions are unequal in size, which is usually the case in psychopathology research. The bottom panel of Figure 23.4 depicts two discrete distributions that are mixed, the larger of which comprises 95% of the combined distribution, and the smaller of which comprises 5%. Although the two distributions are separated by 3.0 within-group standard deviations, there is still no evidence of bimodality in the mixed distribution, which appears to be continuous yet skewed. In fact, the combined distribution is almost identical to a distribution of Social Responsiveness

Figure 23.4 Top panel: Mixture of two normally distributed discrete groups $n = 1000$, each indicated by gray bars and dashed lines. Although the distributions are separated by 2.0 standard deviations, there is no evidence of bimodality in the combined sample, indicated by solid lines and black bars (adapted from Beauchaine, 2003). Bottom panel: Mixture of two normally distributed groups of $n = 950$ (left distribution) and $n = 50$ (right distribution). Although these distributions are separated by 3.0 standard deviations, there is still no evidence of bimodality in the combined sample, which appears to be continuous yet skewed, as indicated by the black bars.

Scale (Constantino, 2002) scores that Constantino and Todd (2003) recently reported in a large twin study of autistic traits. Based on this distribution, the authors concluded that autistic traits are distributed continuously, and that any diagnostic cutoff is therefore arbitrary. As Figure 23.4 indicates, however, such a conclusion is probably unwarranted until more sophisticated data analytic techniques are applied to the question.² Indeed, bimodality provides a very weak test for inferring discrete latent structure.

Figure 23.4 also illustrates why discretely distributed traits and disorders are rarely marked by distinct bound-

²Further recommendations for resolving the latent structure of Autism are presented in later sections.

aries (see also Lilienfeld & Marino, 1995; Meehl, 1995a; Sonuga-Barke, 1998). Here it is useful to consider the difference between latent constructs and manifest indicators. As we noted earlier, the mechanisms responsible for placing individuals into discretely distributed high-risk groups are almost always latent (unobservable) constructs, which are assessed by imperfect manifest (observable) indicators. As we have discussed elsewhere (Beauchaine, 2003b), even single gene disorders are manifested differently across individuals (see also Meehl, 1995a, 2001a). For example, Huntington's chorea, a progressive degenerative disorder of the nervous system that produces emotional instability, mood lability, and motor control difficulties, and is transmitted by an allelic variant of a single dominant gene, has a variable course across individuals. Age of onset, for example, varies considerably from person to person (Brooks, Murphy, Janota, & Lishman, 1987). Thus, despite having a latent genetic etiology that is discrete, manifest indicators of the illness are variable. Additionally, almost all behavioral indicators of psychopathology are measured with imperfect precision and reliability. Because of this, measurement error contributes to distributional overlap even when the latent structure of a trait or disorder is truly discrete. Because measurement precision plays an important role in the efficiency and power of all statistical approaches, we return to it in later sections.

Cluster Analysis

Given the limitations of bimodality for identifying discretely distributed traits, a number of alternative methods have been developed. To date, by far the most popular of these in the psychology and psychiatry literatures is the set of algorithms collectively referred to as *cluster analysis* (Blashfield & Aldenderfer, 1988). In general, these methods divide data sets into multiple partitions, either by maximizing between-group variance or by minimizing within-group variance. Although over 300 such algorithms exist, they can be broadly divided into two overarching categories, each of which we describe briefly (for comprehensive reviews, see Aldenderfer & Blashfield, 1984; Blashfield & Aldenderfer, 1988; Everitt, 1993; Milligan & Cooper, 1987).

Hierarchical agglomerative methods start with each data point representing a unique cluster. Points close to one another in n dimensional space as assessed by correlational, Euclidean, or other distance metrics are combined into progressively larger clusters, a process that is repeated until all data points are included in a single group. When performing a hierarchical agglomerative analysis, the researcher must decide when to stop the process, retaining a

specific number of clusters that presumably best captures homogeneities within subgroups and heterogeneities across subgroups. In psychopathology research, these differences and similarities are typically measured by behavioral symptoms. Hierarchical agglomerative methods are frequently used for exploratory purposes, when the true number of clusters, if any, is unknown.

In contrast to hierarchical agglomerative methods, iterative partitioning, or k -means procedures, begin with a user-specified number of clusters. Individuals are then allocated into clusters and reallocated on successive passes through the data until the within-cluster sums of squares are minimized (Hartigan, 1975). Thus, the researcher determines the preferred number of clusters a priori, and the clustering algorithm creates groups that are as homogeneous as possible.

Clustering algorithms provide two significant advantages for psychopathology research. First, they are multivariate and can therefore accommodate large numbers of variables into a single analysis. Thus, rather than examining one symptom or marker at a time for evidence of discrete latent structure, all relevant symptoms can be analyzed together. Second, they can accommodate models containing any number of homogeneous groups. In contrast, and as described in later sections, taxometric techniques are restricted to instances in which only two groups are hypothesized.³ Despite these strengths, however, clustering algorithms suffer from one very important limitation that has reduced their popularity among psychopathology researchers. Because clustering algorithms are *structure imposing* rather than *structure seeking*, they nearly always identify subgroups within a data set, whether or not those subgroups are truly homogeneous or discrete (Blashfield & Aldenderfer, 1988). For example, when IQ scores from representative samples are cluster analyzed, a two-cluster solution will almost invariably divide the distribution into high- and low-IQ groups, despite the fact that intelligence is continuously distributed in the population (Aldenderfer & Blashfield, 1984). Moreover, consistently effective methods of cluster validation have yet to be identified. Inferring validity by testing for group differences

³In two of his later papers, Meehl (1999, 2001a) described a newly developed technique called TAXSCAN, which does enable researchers to identify multiple discrete traits within a population given sufficiently valid indicators. To date, however, no empirical instantiations of TAXSCAN have appeared in the literature, nor have any large-scale Monte Carlo evaluations of the technique been conducted. For these reasons, we do not consider TAXSCAN in the present chapter.

based on cluster membership, for example, once a common practice among psychopathology researchers, is circular because these differences have been systematically maximized by the clustering algorithm (Aldenderfer & Blashfield, 1984; Blashfield & Aldenderfer, 1988). Similarly, replication does not ensure that clusters are discrete. Clustering algorithms can divide any sample of IQ scores into high and low groups who will differ from one another on numerous external correlates. This does not imply that the groups are discrete. Furthermore, analyses of data sets of known structure indicate that hierarchical agglomerative techniques often fail to identify the correct number of clusters (Krieger & Green, 1999).

These difficulties have led to several efforts to develop both stopping rules for determining the correct number of clusters in a data set and numerical indices of cluster integrity or validity (Milligan, 1981; Milligan & Cooper, 1985). Unfortunately, such methods have been developed using largely nonoverlapping distributions (Blashfield & Aldenderfer, 1988; Waller, Kaiser, Illian, & Manry, 1998), which are rarely observed in psychopathology research. Furthermore, despite clear improvements in recent years, the accuracy of cluster recovery still degrades rather quickly when cluster overlap is increased, and stopping rules remain limited in their ability to determine the presence versus absence of genuinely discrete groups (Atlas & Overall, 1994; Edelbrock, 1979; Grove, 1991; Tonidandel & Overall, 2004). Thus, cutoffs for group membership that are derived from cluster analyses are just as likely to be arbitrarily located along a continuous dimension as they are to distinguish between discretely distributed subgroups. Clustering algorithms therefore provide very weak tests of discrete latent structure (Meehl, 1979). Nevertheless, iterative partitioning methods can be quite accurate in sorting participants into the proper discrete latent class when the existence of that class has been verified beforehand by taxometric methods, which are structure seeking rather than structure imposing (Beauchaine & Beauchaine, 2002).

Mixture Modeling

Mixture modeling refers to a number of related methods that search for homogeneous groups within assumed mixed samples (McLachlan & Basford, 1988). These include *latent class analysis* (e.g., Lazarsfeld & Henry, 1968), which was designed specifically for use with dichotomous and/or Likert data; *latent profile analysis* and *finite mixture analysis* (Gibson, 1959; Lazarsfeld & Henry, 1968; McLachlan & Peel, 2000), which identify latent classes within continuous data; and *growth mixture modeling* (Muthén, 2001; Muthén & Shedden, 1999; Nagin, 1999; Nagin & Tremblay,

2001), which identifies groups from latent growth trajectories in symptoms or other variables of interest over time. Given the capacity to handle longitudinal data, growth mixture modeling approaches have enjoyed rapidly increasing popularity in the developmental psychopathology literature in recent years (e.g., Nagin & Tremblay, 1999; Shaw, Gilliom, Ingoldsby, & Nagin, 2003). Although space constraints preclude us from reviewing the extensive technical bases of these methods, each suffers from the same primary limitation as cluster analysis: They are structure-imposing techniques. Thus, when latent subgroups are identified, it cannot be determined whether or not they are truly discrete. This is true of both traditional approaches to mixture analysis (D. N. Klein & Riso, 1993; McLachlan & Peel, 2000) and newer growth mixture modeling techniques (Bauer & Curran, 2003, 2004). As Bauer and Curran have demonstrated, growth mixture models are prone to identifying spurious latent classes when only one group is represented in a population. Although this does not necessarily undermine the heuristic utility of mixture modeling (Cudeck & Henly, 2003), it clearly limits conclusions that might be drawn about diagnostic boundaries based on results from the techniques.

COHERENT CUT KINETICS

In an effort to address the inherent difficulties faced in identifying discrete psychopathological traits and drawing appropriate diagnostic boundaries, P. E. Meehl and his colleagues invented a set of algorithms collectively referred to as *coherent cut kinetics* (CCKs; Grove & Meehl, 1993; Meehl, 1973b, 1995a; Meehl & Yonce, 1994, 1996; Waller & Meehl, 1998). These methods were designed with the explicit objective of identifying discrete groups when they exist in a larger population, without the false-positive problem that characterizes most alternative approaches. The term CCK is intended to capture common attributes of the algorithms (Meehl & Yonce, 1994, 1996; Waller & Meehl, 1998). Each includes analysis of the statistical behavior of one or more variables in successive regions (cuts) of an input variable. These cuts are moved (kinetics) across the entire range of the input variable, and numerical values of latent parameters are estimated. If a discrete subgroup or *taxon* is present and the variables chosen are valid indicators of that taxon, estimates of these parameters are consistent (coherent) across analyses. In total, Meehl and colleagues specified 13 such taxometric procedures.

The impetus for developing taxometric methods was to test Meehl's (1962) diathesis-stress model of Schizophrenia.

Meehl hypothesized that a genetic vulnerability, which he called *schizotaxia*, was transmitted through a single dominant gene that was not fully penetrant. In other words, the schizotaxic genotype was thought to be a necessary but insufficient cause of Schizophrenia, resulting in the disorder for only a subset of genetically susceptible people. He also believed that a carefully selected group of observable phenotypic markers, expressed as *schizotypy*, could be used to identify the genetic vulnerability, whether or not a person developed Schizophrenia. After observing hundreds of patients and their family members in clinical contexts, Meehl (1962) outlined four putative schizotypic phenotypes as markers of the schizotaxic genotype: *interpersonal aversiveness*, or social fear, distrust, and anticipation of rejection; *ambivalence*, or concurrent motivation toward interpersonal approach and withdrawal; *cognitive slippage*, or loose control of associations; and *anhedonia*, or a limited capacity to experience pleasure.⁴ Of note, in the intervening years since Meehl proposed his theory, a number of promising endophenotypic markers of genetic vulnerability for Schizophrenia have also been specified. As outlined in the introduction to this chapter, increased blood oxygenation in the right dorso-lateral prefrontal cortex during working memory tasks has been identified in nonaffected siblings of patients with Schizophrenia (Callicott et al., 2003; Manoach et al., 1999). Similarly, smooth pursuit and saccade eye tracking abnormalities are observed in both patients with Schizophrenia and their first-degree relatives (Avila, McMahon, Elliott, & Thaker, 2002; Curtis, Calkins, Grove, Feil, & Iacono, 2001; Levy, Holzman, Matthysse, & Mendell, 1993).

Meehl understood that phenotypes are measured with considerable error, and that the distribution of schizotypic traits among genetic positives would therefore overlap substantially with the distribution of similar traits in the population. Given this, new methods aimed at disentangling such mixed distributions would need to be developed. The taxometric procedures we describe are the result of an over-30-year effort by Meehl and his colleagues to address this problem. Although it is now recognized that Schizophrenia is a polygenically determined disorder, schizotypy has been shown in numerous studies using CCK procedures to be distributed as a discrete latent class among genetically vulner-

able individuals (Blanchard, Gangestad, Brown, & Horan, 2000; Erlenmeyer-Kimling, Golden, & Cornblatt, 1989; Golden & Meehl, 1979; Horan, Blanchard, Gangestad, & Kwapił, 2004; Korfine & Lenzenweger, 1995; Lenzenweger, 1999; Lenzenweger & Korfine, 1992, 1995; Tyrka, Cannon, et al., 1995; Tyrka, Haslam, & Cannon, 1995).

In the next section, we describe four of Meehl's taxometric algorithms. We begin with MAXimum SLOPE (MAXSLOPE), a less popular taxometric procedure that is nevertheless informative pedagogically. We then describe three commonly used taxometric procedures including MAXimum COVariance (MAXCOV), MAXimum EIGenvalue (MAXEIG), and Mean Above Minus Below A sliding Cut (MAMBAC). Because comprehensive descriptions of these procedures are readily available, our presentations are purposefully brief.

MAXSLOPE

In the MAXSLOPE procedure (Grove & Meehl, 1993), putative indicators of taxon group membership are plotted against one another, and a smoothed regression function is fitted to the scatter plot. The regression slope (dy/dx) is then calculated in successive intervals of the input (x) variable. An example appears in Figure 23.5, where a hypothetical plot of ambivalence and eye-tracking abnormality is presented. When a taxon group is present and an adequate

Figure 23.5 Illustration of the MAXSLOPE procedure using a fictitious bivariate distribution of ambivalence and eye tracking abnormality. The slope of the regression function is maximized at the point that best discriminates schizotypes ($n = 100$), indicated by solid dots, from controls ($n = 900$), indicated by crosses. This point on x is referred to as the hitmax cut. When no taxon group is present, the regression line is flat. Note that despite an effect size (d) of 2.0, the marginal univariate distributions are near normal, with no evidence of bimodality.

⁴As we have described elsewhere (Beauchaine, 2003b), Meehl (1975, 1989, 1990) eventually withdrew the proposition that anhedonia marks a genetic vulnerability for Schizophrenia, suggesting instead that hypohedonia falls at one end of a hedonic capacity spectrum. However, recent taxometric analyses of the anhedonia construct suggest that Meehl's (1962) original thesis may have been correct (Blanchard et al., 2000).

effect size is observed, then a discontinuity appears in the regression function, which is maximized at the level of variable x (eye-tracking abnormality) that best discriminates the taxon group from the *complement class* (nontaxon group). Put another way, the correlation between eye-tracking abnormality (x) and ambivalence (y), represented by the regression slope, is highest at the value of x that maximizes diagnostic accuracy. This is referred to as the *hitmax* cut.

There are a number of points to be made about this example that generalize to more complex CCK procedures described later. First, both the inflection in the regression slope and the observed correlation, or standardized covariance between eye-tracking abnormality and ambivalence ($r = .2$), are caused entirely by mixing two discrete groups. In either group, the covariance between variables is zero. Covariation between variables that is produced by mixing of a taxon group and its complement class is described in the general covariance mixture theorem (Meehl, 1995a, p. 271; Meehl & Yonce, 1996, p. 1097):

$$\text{cov}(xy) = p\text{cov}_t(xy) + pq(x_t - x_c)(y_t - y_c) \quad (1)$$

where $\text{cov}_t(xy)$ represents the covariance of variables x and y in the taxon group, $\text{cov}_c(xy)$ represents the covariance of variables x and y in the complement class, p and q represent the proportions of taxon group and complement class members, respectively, in the bivariate sample, and t and c represent the means of variable x and y in group i . Typically, the simplifying assumption is made that within-group correlations are zero (conditional independence), and the first two terms are dropped.⁵ Along with some auxiliary formulae, this theorem provides the mathematical basis for estimating latent parameters, including the taxon base rate and both the taxon and complement class means.

It is worth noting that even when a taxon is detected, assigning individuals to groups remains probabilistic.

⁵The assumption of zero nuisance correlation is referred to as conditional independence in the latent class analysis literature. In practice, within-class correlations are likely to be nonzero. However, Monte Carlo studies have revealed that under most conditions, CCKs are robust when such *nuisance correlations* approach and in some cases exceed .30 (Beauchaine & Beauchaine, 2002; Cleland & Haslam, 1996; Haslam & Cleland, 1996; Meehl, 1995b).

As noted by Bauer and Curran (2004), a multivariate generalization of the general covariance mixture theorem underlies latent profile analysis models, which also make the assumption that all observed covariances among k variables are the result of admixing discrete groups.

Thus, it is not possible to be perfectly accurate in assigning individuals to groups, as long as those groups overlap. Nevertheless, the *hitmax* cut provides an objective boundary that optimizes diagnostic accuracy. The location of this boundary is determined by the base rate of the taxon group in the population. When the base rate is 50, for example, the *hitmax* cut appears near the grand mean on variable x . When the base rate is lower, such as .10 in the present example, the *hitmax* cut shifts toward the right.

MAXCOV

Conceptually related to MAXSLOPE, MAXCOV (Meehl, 1973b; Meehl & Yonce, 1996; Waller & Meehl, 1998) is the most thoroughly evaluated and most commonly used taxometric procedure (Haslam & Kim, 2002). It assesses the covariance of two putative indicators of taxon group membership across successive intervals of a third indicator, with a smoothed regression function fitted through the resulting covariance values. For example, suppose that a third schizotypy indicator, such as anhedonia, is available for analysis. We can now examine the covariance of eye-tracking abnormality (x) and ambivalence (y) within successive intervals of anhedonia (z). The previously presented scatter plot of ambivalence and eye-tracking abnormality is reproduced in the top left panel of Figure 23.6, with the covariance of both variables across intervals of anhedonia appearing below. If a taxon is present and the effect size is adequate, then a clear peak is observed in the covariance of variables x (eye-tracking abnormality) and y (ambivalence), which is maximized at the level of variable z (anhedonia) that best discriminates between groups. This is demonstrated in the bottom left panel of Figure 23.6. As with the MAXSLOPE example, this value is referred to as the *hitmax* interval because group assignment of individuals is optimized at this boundary. The MAXCOV peak shifts toward the left at higher taxon base rates. When no taxon is present, the covariance function of variables x and y across intervals of z is relatively flat, as shown in the bottom right panel of Figure 23.6.

For each three-way combination of indicators, MAXCOV produces estimates of several latent distributional parameters, including the *hitmax* value, the taxon base rate, the sample sizes of the taxon group and complement class, and the false-positive and false-negative rates of group membership assignments. Furthermore, MAXCOV can be used to assign individuals to the taxon group and complement class using Bayes's theorem (see Beauchaine

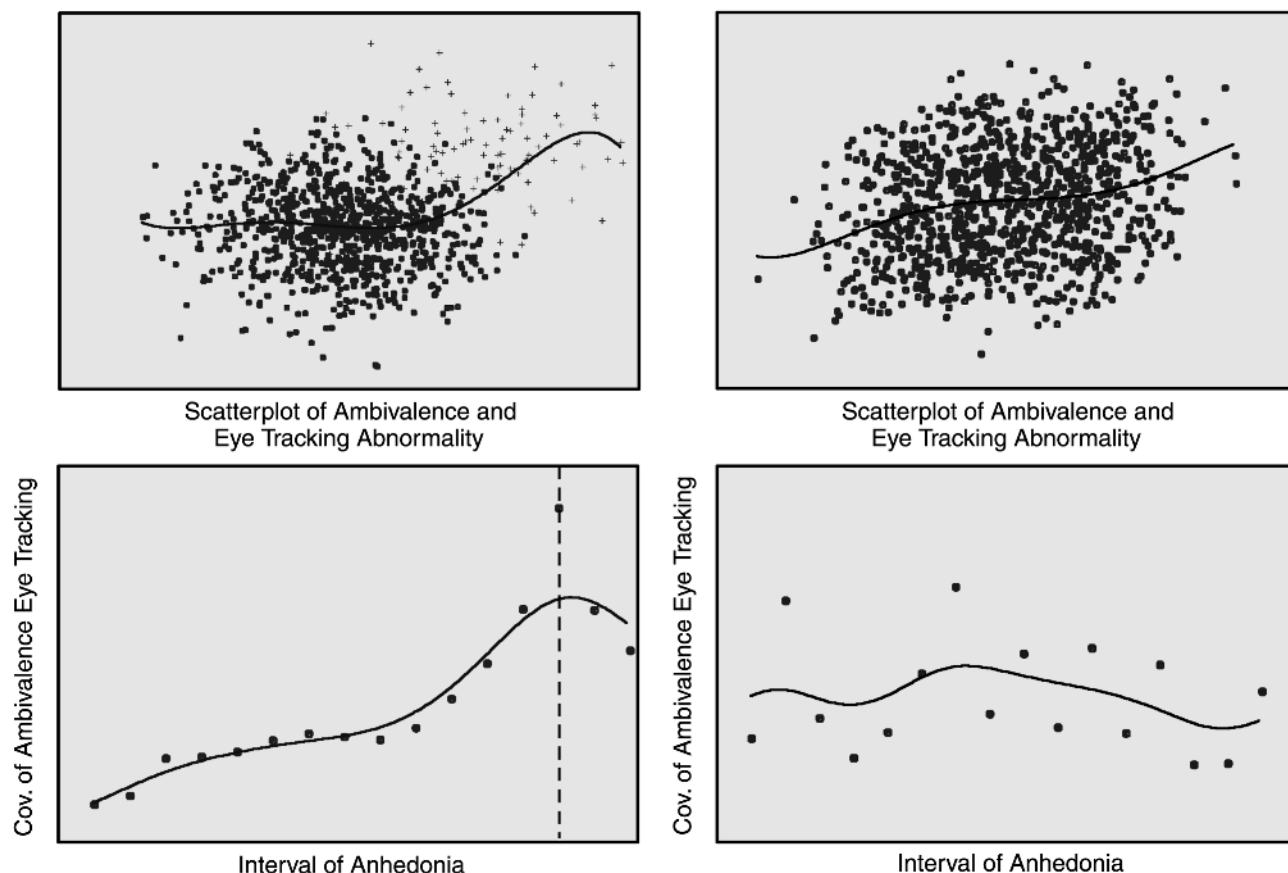

Figure 23.6 Illustration of the MAXCOV procedure using fictitious distributions of ambivalence and eye tracking abnormality across successive intervals of anhedonia. For comparison purposes, the top panels represent scatterplots of taxonic data (left) and continuous data (right), with MAXSLOPE functions fitted to each. MAXCOV functions are presented in the bottom panels. Note that in the taxonic case (left) the covariance between ambivalence and eye tracking abnormality is maximized within the interval of anhedonia that best discriminates between schizotypes ($n = 100$), indicated by solid dots, from controls ($n = 900$), indicated by open squares. This is referred to as the hitmax interval, as indicated by the dashed line. In the continuous case (right) there is no clear peak in the covariance function. Note the agreement between MAXSLOPE and MAXCOV in identifying the hitmax value. The bivariate correlation (r) is .20 in both samples.

& Beauchaine, 2002; Meehl & Yonce, 1996; Waller & Meehl, 1998).

MAXEIG

Although MAXEIG (Waller & Meehl, 1998) has been used less frequently than MAXCOV (Haslam & Kim, 2002), it has recently gained in popularity, with some authors advocating that it become the CCK of choice in taxometrics research (e.g., J. Ruscio & Ruscio, 2004a). For reasons stated in later sections, we do not share this opinion. Nevertheless, MAXEIG can be a useful complement to other CCK procedures.

MAXEIG operates on any number of putative taxon indicators greater than or equal to three. One variable serves as the “input” indicator, and the remaining variables serve

as “output” indicators. The input variable is divided into a series of overlapping windows, and the variance-covariance matrix of the output variables is computed within each. The diagonal elements (variances) of the variance-covariance matrix are replaced with zeros, and the first eigenvalue from a principal components analysis is extracted. These eigenvalues are then plotted across the entire range of the input variable. Similar to the case of MAXCOV, a peak is observed in the MAXEIG function if a taxon is present in the multivariate data set. This is because larger eigenvalues indicate greater intercorrelations among the output variables. When such intercorrelations are driven by the admixture of two discrete groups, the eigenvalues are largest in the hitmax window, which again indicates the point along the input variable that best discriminates between taxon group and complement class

Figure 23.7 Illustration of the MAXEIG procedure using fictitious distributions of ambivalence, eye tracking abnormality, anhedonia, and social anxiety. Anhedonia serves as the input (x) variable, along which eigenvalues from the ambivalence/eye tracking abnormality/working memory impairment covariance matrix are plotted in successive windows. The eigenvalue function is maximized in the window of x that best discriminates between schizotypes ($n = 100$) and controls ($n = 900$). In the continuous case (not pictured), eigenvalues in successive overlapping windows tend to fluctuate around a single number.

members. A sample MAXEIG plot is presented in Figure 23.7, which was derived from the schizotypy example used in earlier sections.

MAMBAC

To date, MAMBAC (Meehl, 1995a; Meehl & Yonce, 1994) is the second most frequently used taxometric algorithm (Haslam & Kim, 2002). When using MAMBAC, indicators are analyzed in variable pairs. One variable is first sorted, which also sorts the other if both are valid markers of the analyzed trait. To continue with the example of schizotypy, sorting on anhedonia (x) also sorts on eye-tracking abnormality (y). Next, a sliding cut is moved across all values of anhedonia, and the mean of eye-tracking abnormality is calculated both above and below this cut. At each point, the mean above the cut is subtracted from the mean below the cut, and the resulting values are plotted. If a taxon group is present and the effect size is sufficient, then a peak is produced in the MAMBAC function at the value of anhedonia (x) that best discriminates between those in the taxon group and those in the complement class. In contrast, continuously distributed data produce U-shaped MAMBAC functions.

Figure 23.8 depicts all pairwise combinations of six indicators for both taxonic and dimensional data sets from a recent experiment conducted in our lab (Beauchaine & Waters, 2003). For the present discussion, details about the experiment are unimportant. Rather, we present the MAMBAC plots to illustrate the clear difference between functions derived from discrete versus dimensional data. As we shall see in later sections, the ability to plot MAMBAC curves in this fashion offers significant advantages when screening candidate indicators for additional taxometric analyses using other CCK algorithms. We now turn our attention to recommendations for conducting taxometrics research.

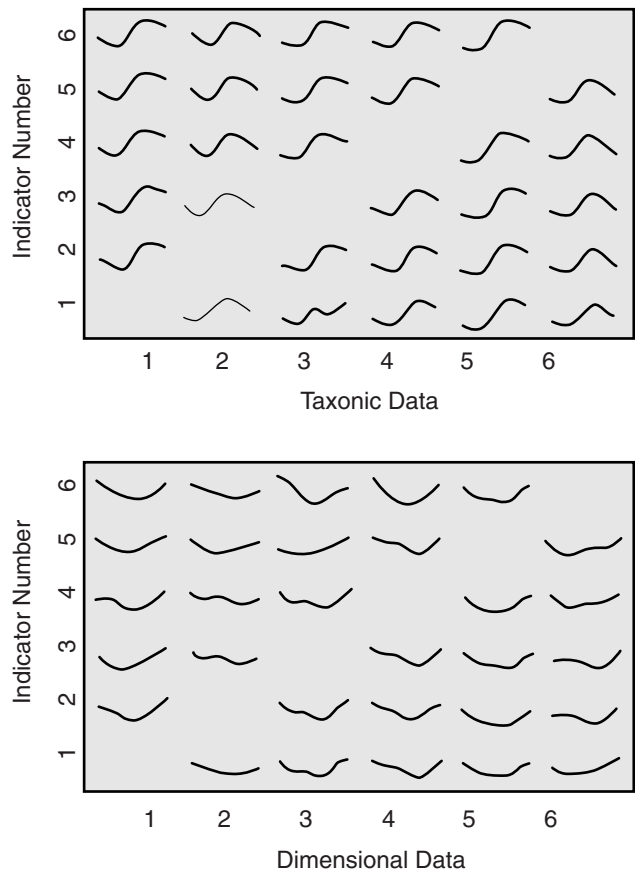

Figure 23.8 Illustration of the MAMBAC procedure. The top panel represents all pairwise MAMBAC plots from taxonic data (total $n = 1125$) with a base rate of .34. Note the consistency of the location of peaks across MAMBAC runs. The bottom panel represents all pairwise MAMBAC plots from dimensional data (total $n = 1125$). In contrast to the plots derived from taxonic data, all MAMBAC functions from dimensional data are dish-shaped. Source: "Pseudotaxonicity in MAMBAC and MAXCOV Analyses of Rating Scale Data: Turning Continua into Classes by Manipulating Observer's Expectations," by T. P. Beauchaine, and E. Waters, 2003, *Psychological Methods*, 8, pp. 3–15.

TESTING TAXONIC CONJECTURES

Although taxometric methods have been used infrequently by developmental psychopathologists (Beauchaine, 2003b), they now commonly appear in the adult psychopathology literature. As a reflection of their growing popularity, recent special sections devoted to taxometrics have appeared in both the *Journal of Abnormal Psychology* (Cole & Baker, 2004) and *Clinical Psychology Science and Practice* (Barlow, 2001). In a comprehensive review of empirical taxometrics investigations, Haslam and Kim (2002) identified 66 separate studies that have used at least one CCK procedure. Moreover, a PsychINFO database search conducted on July 27, 2004, using the keywords MAMBAC, MAXCOV, MAXEIG, and taxometric yielded 127 hits. Thus, it is clear that CCKs are increasing in popularity. Although only a handful of these studies have included child or adolescent samples or addressed developmental questions, there is much to be learned from the adult psychopathology literature about conducting taxometrics research.

In the following sections, we discuss both the planning and implementation of taxometric analyses. To date, most taxometrics studies have been conducted using large data sets of convenience, with primarily self-report and informant-report measures of symptoms derived from *DSM-IV* criterion lists. In light of our discussion in the introduction to this chapter, this general approach poses a number of problems for identifying latent vulnerability traits that predispose individuals to psychopathology. Indeed, we argue that the greatest potential of taxometric methods lies in identifying such vulnerability traits *before* psychopathological outcomes emerge.

Selecting Candidate Indicators

Given the advantages of identifying latent vulnerability traits premorbidly, perhaps the most important step in conducting taxometrics research is selecting viable candidate indicators that are sensitive to genotypic susceptibility. In doing so, several important issues must be considered. We discuss these in turn.

From Behavioral Syndromes to Latent Vulnerabilities

As we noted earlier in this chapter, developmental psychopathologists have long emphasized the importance of identifying traits that place individuals at risk for psychopathology, recognizing that diagnostic syndromes are

often insufficient for capturing life course trajectories in behavioral functioning. This is instantiated in the notion of *heterotypic continuity*, which refers to cases in which a single etiologic vulnerability gives rise to seemingly different disorders across subsequent developmental periods. Seriously delinquent adult males, for example, are likely to have followed a developmental progression that began with incipient hyperactive/impulsive behaviors in toddlerhood, followed by Oppositional Defiant Disorder emerging in preschool, early-onset CD emerging in elementary school, and both substance abuse and Antisocial Personality Disorder (ASPD) emerging in adolescence and adulthood (see Loeber & Hay, 1997; Loeber & Keenan, 1994; Lynam, 1996, 1998). Given that substance use disorders are diagnosed separately for each drug, a delinquent male on such a trajectory could qualify for five or more diagnoses by the time he reaches early adulthood. In previous sections, we discussed how an overreliance on behavioral syndromes obscures etiological heterogeneity within groups of people afflicted with psychiatric disorders. This example demonstrates that focusing on behavioral syndromes can also obscure developmental heterogeneity in the expression of psychopathological vulnerability traits within individuals. Indeed, full appreciation of heterotypic continuity among externalizing disorders followed nearly a century of systematic efforts to study delinquency, in part because most researchers specialize in single behavioral syndromes.

Recently, however, Krueger and colleagues (2002) demonstrated that comorbidity among disinhibition, conduct problems, antisocial behavior, alcohol dependence, and drug dependence is accounted for almost entirely by a single underlying latent genetic vulnerability. Figure 23.9 depicts the common pathway model of externalizing disorders among the large sample of twins in the Krueger et al. study. Note that additive genetic effects accounted for 81% of the variance in the latent vulnerability for externalizing disorders. At the behavioral syndrome level, however, shared and nonshared environmental contributions were larger than genetic effects. This suggests that the overt expression of the latent vulnerability trait depends on environmental opportunities and that the study of behavioral syndromes such as drug dependence and ASPD fails to capture the ontology of externalizing psychopathology. As Skuse (2001, p. 395) recently noted, "A focus on traits, rather than syndromes, is appropriate and could in due course contribute to the redefinition of traditional psychiatric syndromes."

This discussion suggests that researchers who are interested in uncovering the latent structure of vulnerability

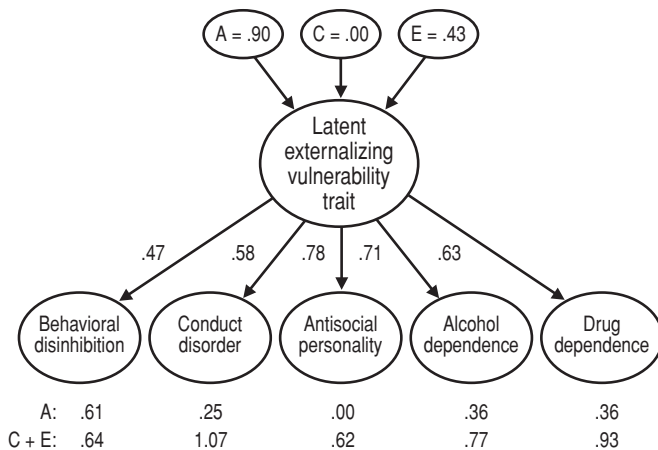

Figure 23.9 Genetic and environmental effects on five externalizing behavioral syndromes, and their loadings on a common latent vulnerability. A = Additive genetic effects; C = Shared environmental effects; E = Nonshared environmental effects. Adapted from “Etiologic Connections among Substance Dependence, Antisocial Behavior, and Personality: Modeling the Externalizing Spectrum,” by R. F. Krueger et al., 2002, *Journal of Abnormal Psychology*, 111, pp. 411–424.

for externalizing disorders should include indicators that cut across traditional psychiatric boundaries. To date, several studies have addressed the question of whether antisocial behavior is distributed discretely, yet each has included rating scales of particular behavioral syndromes rather than broader vulnerability traits. Harris, Rice, and Quinsey (1994) found a discrete latent class of psychopaths among institutionalized offenders using items from the Psychopathy Checklist (Hare et al., 1990), a finding that was later replicated using both psychopathic features and *DSM-IV* ASPD criteria (Skilling, Harris, Rice, & Quinsey, 2001). Moreover, Skilling, Quinsey, and Craig (2001) reported evidence for an antisocial behavior taxon in a large community sample of fourth- through eighth-grade boys, as did Ayers, Haslam, Bernstein, Tryon, and Handelsman (1999) in a large sample of adults. Interestingly, items that were most useful in identifying the latent taxon from the Psychopathy Checklist were those representing chronic, childhood-onset delinquent behavior (Haslam, 2003), suggesting that the group identified were those on the life-course-persistent trajectory described earlier. Although there are problems with using strictly rating scale data in taxometrics research (Beauchaine & Waters, 2003), these findings suggest that additional studies should be conducted to explore the la-

tent structure of vulnerability to externalizing disorders. Ideally, these research efforts will include endophenotypic markers with potential to capture the latent genetic vulnerability to externalizing syndromes described by Krueger et al. (2002), with greater precision than behavioral rating scales provide (see later discussion).

From Phenotype to Endophenotype

As we argued earlier, and as recently emphasized by a number of authors (Castellanos & Tannock, 2002; Gottesman & Gould, 2003; Skuse, 2001), identifying latent vulnerabilities for psychopathology will almost certainly be facilitated by including endophenotypic markers of risk in future research. Continuing with the example of externalizing disorders, Patrick et al. (2005) recently demonstrated that reduced amplitude of the P300 event-related brain potential marks vulnerability across the entire externalizing spectrum among adolescent males. Although reduced P300 amplitude has long been associated with genetic vulnerability for alcoholism (Begleiter, Porjesz, Bihari, & Kissin, 1984; Porjesz, Begleiter, & Garozzo, 1980), it had not previously been explored as a broader marker of risk. In our own lab, we have consistently found attenuated sympathetic nervous system-linked cardiac reactivity to monetary incentives among adolescents with early-onset CD and among children as young as age 4 who are at risk for conduct problems (Beauchaine, 2003a, 2004; Beauchaine, Katkin, Strassberg, & Snarr, 2001; Beauchaine, Gatzke-Kopp & Mead, in press; Crowell, Beauchaine, Gatzke-Kopp, Sylvers, & Mead, in press). Moreover, numerous studies have demonstrated low levels of electrodermal responding among impulsive, aggressive, and delinquent males, both at baseline and in response to mild punishment (see Beauchaine, 2001). Variables such as these are ideal candidates for future taxometrics research designed to determine whether the antisocial taxon can be identified before psychopathic and antisocial behavior patterns are established. It is well-known that empirically supported interventions for conduct problems are more effective with younger as opposed to older children (e.g., Dishion & Patterson, 1992; Ruma, Burke, & Thompson, 1996). Premorbid identification of latent genetic vulnerability may therefore provide for more effective prevention and intervention programs. In later sections, we outline how identification of latent genetic risk for Schizophrenia can already contribute to enhanced prevention of first-episode psychosis.

Indicator Validity

The term validity has multiple meanings in the behavioral sciences, some of which were discussed in earlier sections. In the context of taxometrics research, validity refers to the degree to which a variable distinguishes between a taxon group and its complement class (Cole, 2004; Meehl, 1995a). For example, consistent with Meehl's (1962) original thesis, taxometric studies of schizotypy have repeatedly demonstrated that anhedonia, social withdrawal, and perceptual aberration mark a discretely distributed group of individuals who are at heightened risk for developing Schizophrenia (Blanchard et al., 2000; Erlenmeyer-Kimling et al., 1989; Golden & Meehl, 1979; Korfine & Lenzenweger, 1995; Lenzenweger, 1999; Lenzenweger & Korfine, 1992; Tyrka, Cannon, et al., 1995). Thus, each of these indicators is of established validity. It is important to remember, however, that performing a taxometric analysis is a bootstrapping endeavor, so one cannot know the validity of a marker *a priori*. Given this, candidate indicators should be selected based on strong theoretical considerations (Beauchaine & Waters, 2003; Lenzenweger, 2004; Meehl, 1999; Waters & Beauchaine, 2003). Otherwise, failure to detect a taxon could be the result of using invalid indicators.

In recent years, it has become common for researchers to perform taxometric analyses on large data sets that were collected for other purposes. Often, these data sets contain rating scales assessing all symptoms in a diagnostic class, which are subjected to one or more CCK procedures. Among several problems with this approach is the lack of attention paid to indicator validity. When a taxon exists, some markers are more valid than others and are therefore more effective in distinguishing group members from complement class members. When invalid indicators are used, taxa simply go undetected.

One example of the importance of carefully selecting indicators comes from taxometric research on depression, where several studies have yielded evidence of a discretely distributed depressive taxon group in both adolescent and adult samples (Ambrosini, Bennett, Cleland, & Haslam, 2002; Beach & Amir, 2003; Grove et al., 1987; Haslam & Beck, 1994). In each of these studies, identification of the depressive taxon was contingent on the use of melancholic or vegetative symptoms including psychomotor retardation, agitation, anhedonia, sleep disturbance, loss of weight, loss of appetite, and diminished libido. Such somatic symptoms have been proposed to mark disturbances in homeostatic regulation characteristic of endogenous depression.

In taxometric analyses conducted that have not distinguished melancholic symptoms from symptoms of distress, no taxon has been found (Beach & Amir, 2003; Haslam & Beck, 1994; J. Ruscio & Ruscio, 2000).⁶ Thus, when both valid (melancholic) and invalid (distress) markers of endogenous depression are included in the same analysis, the taxon goes undetected. This is because CCKs require that each and every indicator be of high validity. We illustrate this in Figure 23.10, where all three-way combinations of MAXCOV plots are presented for two artificially created multivariate data sets, each with three indicators. The left panels depict plots in which all three indicators (x , y , and z) mark a .10 base rate latent taxon with high validity, as indexed by 2.0 standard deviations of separation (Cohen's d) between the taxon group and complement class means. In contrast, the right panels depict MAXCOV plots in which one indicator (x) was replaced with a fourth indicator (w) of low validity ($d = .50$). Note that there is no evidence of a latent taxon in the right three panels despite two out of three variables being high in validity. Moreover, estimates of the taxon base rate are widely divergent and inaccurate. This suggests that great care should be taken in the selection of putative indicators for taxometric analyses and that atheoretical investigations that include all available markers are likely to be ineffective in identifying existing taxa (see also Lenzenweger, 2004).

⁶Recently, J. Ruscio et al. (2004) have challenged the existence of an endogenous depression taxon, arguing that indicator skew is likely responsible for false-positive identifications of discrete latent structure in each of the studies cited. This claim is based on analyses using a technique advanced by A. Ruscio and Ruscio (2002; J. Ruscio & Ruscio, 2004a) in which both latent dimensional and latent taxonic data sets are simulated to match observed data parameters. Taxometric analyses are then conducted on all three data sets (observed, simulated dimensional, simulated taxonic), and inferences are drawn regarding latent structure based on whether results obtained from the observed data are more similar to results obtained from the simulated dimensional or simulated taxonic data. However, when J. Ruscio et al. reported their results refuting the endogenous depressive taxon, no studies had been published describing the operating characteristics of the simulated comparison technique. Since that time, a large-scale Monte Carlo analysis (Beach, Amir, & Bau, in press) has revealed that the method is prone to false negatives when the taxon base rate is low and skew is high—precisely the conditions for endogenous depression and for most other psychiatric taxa. For these reasons, J. Ruscio et al. may have been mistaken in refuting the endogenous depression taxon, and their technique will not be considered further in this chapter.

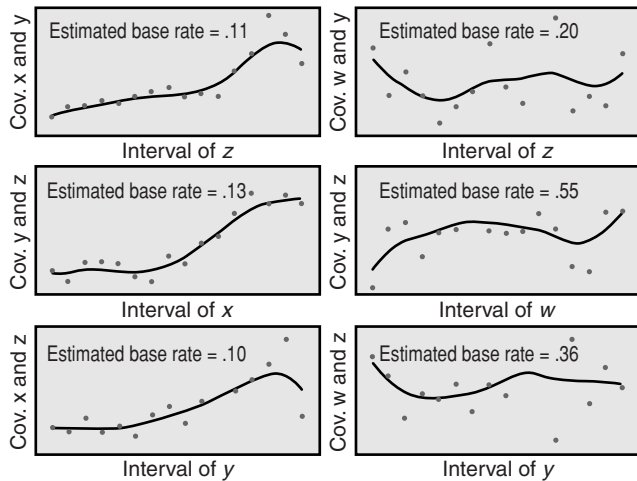

Figure 23.10 Effects on MAXCOV analyses of adding one invalid indicator. The left three panels depict all MAXCOV plots for three indicators (x , y , z) of high validity (Cohen's $d = 2.0$). The right three panels depict all MAXCOV plots with variable x replaced with an indicator (w) of low validity ($d = .50$). In both cases the overall sample size is 1000 with a taxon base rate of .10. Note the effect on MAXCOV-derived base rate estimates of including just one indicator of low validity.

Measurement Precision

To date, most researchers have also paid little attention to measurement precision when selecting candidate indicators for taxometric analyses. This is unfortunate because precision has a profound effect on indicator validity. Precision refers to our ability to measure a construct without error. Here it is useful to recall the distinctions among nominal, ordinal, interval, and ratio scales of measurement offered by Stevens (1951). *Nominal* scales are strictly categorical and do not allow for statements of inequality. For example, it makes little sense to suggest that one zip code is more or less than another zip code; they simply refer to different geographic locations. In contrast, *ordinal* measurement scales do imply quantitative differences between measured attributes, yet they do not allow the magnitude of those differences to be specified in absolute terms. Likert scales in which respondents rate a statement as “strongly agree,” “agree,” “neutral,” “disagree,” or “strongly disagree” represent an ordinal level of measurement. Although it may be appropriate to state that “strongly agree” > “agree” and that “disagree” > “strongly disagree,” the distance between anchors cannot be assumed to be equal, nor can we necessarily assume that “agree” = “agree” from one question to another. For these reasons, we should be wary about performing complex mathematical and/or statistical operations on ordinal scales. *Interval* and *ratio* scales do provide equal intervals between anchors and therefore allow for

strong statements about equality and inequality and for much more sophisticated mathematical and statistical transformations and operations.

Of particular importance, all data collected via rating scales carry at best ordinal-level measurement precision. Moreover, Likert ratings on attributes such as personality and psychopathology traits, which require significant inference on the part of raters, contain up to 50% error variance, reducing precision substantially (Hoyt & Kerns, 1999). The relation between measurement error and precision is depicted in Figure 23.11, where two pairs of distributions appear. In the left pair, an effect size (d) of .5 separates the group means, resulting in 67% overlap. In contrast, in the right pair, an effect size of 2.0 separates the group means, resulting in only 19% overlap. Note that the distance between means is identical in both cases. What is different is that the right distributions contain considerably less measurement error, as indicated by narrower dispersion along the x axis. This illustrates the importance of seeking precise measures for taxometric analyses, where large effect sizes are *essential* for CCKs to be effective. Extensive Monte Carlo simulations have revealed that MAXCOV, the most commonly used algorithm, is effective in detecting latent taxa only at effect sizes (d) of 1.2 or larger (Beauchaine & Beauchaine, 2002; Meehl, 1995a). Recall that a typical effect size in psychological research is around .6, or half this size (Cohen, 1988). Thus, existing taxa cannot be detected if the taxon group and complement class means are separated by anything less than a very large effect.

One strategy for increasing measurement precision is to combine items into scales, either by aggregating based on conceptual considerations (J. Ruscio & Ruscio, 2004b) or

Figure 23.11 Relationship between measurement precision and effect size. The left pair of distributions are separated by .5 standard deviations, a typical effect size in psychology, and overlap 67%. The right distributions are separated by 2.0 standard deviations, and overlap only 19%. Although the distance between means is equal in both cases, a larger effect size is obtained when measurement error, indicated by distributional dispersion, is reduced.

by factor analyzing individual items into common components, which reduces measurement error by isolating shared variance (see Nunnally & Bernstein, 1994). Using factor scores as indicators can therefore enhance the sensitivity of CCKs to underlying taxa. It should be noted, however, that using all extracted factors from a large pool of items is a poor strategy for taxometrics research because each factor is likely to capture a different facet of behavior among a given sample. For example, although the Child Behavior Checklist (CBCL; Achenbach, 1991) was constructed using factor analysis, one would not include factor scores from conceptually unrelated scales (e.g., withdrawn, aggressive) in a single taxometric analysis, because each indicator should be conceptually related to the putative latent taxon. However, it would be perfectly reasonable to use factor scores on related but different scales from measures such as the CBCL and the Eyberg Child Behavior Inventory (Robinson, Eyberg, & Ross, 1980). Unfortunately, many taxometrics investigations conducted to date have used individual scale items. Although this strategy increases the number of indicators available for analysis, it is likely to result in underpowered tests for latent taxonic structure due to low measurement precision.

A second strategy for reducing measurement error, although one that has not been used to date in taxometrics research, is to assess growth in the same construct over time. It is well-known that each additional assessment point included in a growth parameter increases measurement precision (Rogosa, Brandt, & Zimowski, 1982). This is why sex differences in the growth trajectories of depressive symptoms emerge *before* mean differences can be detected (Cole et al., 2002). Longitudinal growth trajectories may therefore be useful in future taxometrics investigations. Thus far, only one longitudinal taxometric study has been conducted, and growth trajectories were not used as indicators (Tyrka, Haslam, et al., 1995). However, a number of large longitudinal data sets, such as the Pittsburgh Youth Study (see Loeber, Farrington, Stouthamer-Loeber, & Van Kammen, 1998), exist that might be used to address questions concerning the development of discretely distributed psychopathological traits.

However potentially useful, none of these ad hoc strategies can replace deliberate and careful selection of precise measures. For this reason, a consensus has begun to emerge among taxometrics researchers regarding the advantages of using indicators that are both continuous and objective (Beauchaine, 2003b; Lenzenweger, 2004; Meehl, 1995a; Waters & Beauchaine, 2003). Such measures are inherently more precise than Likert scales obtained from either self-report or observer report. Note that this provides yet another

reason to search for endophenotypic markers of risk for use in taxometrics studies of psychopathology, as most biological measures carry ratio-level precision and yield continuous scores. Nevertheless, other potential data sources that carry interval or ratio scale properties, such as objective behavior observations, might also be used. We want to emphasize that we are not advocating that psychometric data be eliminated from taxometrics research entirely. Rather, we are suggesting that as many data sources as possible be included.

Number of Indicators

Using the methods described in this chapter, taxometric inferences can be investigated with as few as two indicators (with the MAXSLOPE procedure). However, we are aware of no published studies in which so few indicators were used, and we do not recommend conducting taxometrics research with fewer than five to six indicators (or more if possible). Monte Carlo studies with MAXCOV in particular suggest that both taxon identification and classification accuracy increase markedly with more available indicators, with an asymptote around seven to eight (Beauchaine & Beauchaine, 2002). Although few studies have used this many indicators (for exceptions, see Harris et al., 1994; Korfine & Lenzenweger, 1995; Waller, Putnam, & Carlson, 1996; Waller & Ross, 1997), it is clear that power to detect latent taxa is optimized in this range. Given that some potential indicators are almost surely to be dropped from most taxometric analyses (see later discussion), our advice is to include as many items as possible in the planning stages of a study. This raises the question of whether item redundancy is appropriate. In psychometric theory, *redundant* variables are those that mark the same latent construct. In this sense, multiple redundant indicators are preferred because they allow us to increase measurement precision, as described earlier. Thus, redundancy is welcome in taxometrics research, provided that variables from alternative levels of analysis (e.g., biological, psychological, behavior observation) are represented in the item pool. Although some authors have argued against item redundancy in taxometrics research (J. Ruscio & Ruscio, 2004b), our reading suggests that they are equating redundancy with item independence. In contrast, we use the term redundancy in the strict psychometric sense.

Sample Size

Monte Carlo studies have established clear guidelines for the minimum sample size required when using the MAMBAC and MAXCOV algorithms, suggesting a lower bound for reliable taxon detection of about $n = 200$ with highly valid indicators (e.g., Beauchaine & Beauchaine, 2002;

Meehl, 1995a; Meehl & Yonce, 1994). However, given that indicator validity is likely to vary considerably in any given study, sample sizes of 300 or more are preferred. Thus, many data sets are unsuitable for taxometric analyses, aside from those derived from epidemiological samples. Yet, if variables are chosen carefully across studies and equivalent sampling procedures are used, data sets may be combined to pursue taxonic questions. Additionally, evidence presented by Waller and Meehl (1998) provides preliminary support for using smaller samples with the MAXEIG algorithm. To date, however, the operating characteristics of MAXEIG remain largely unexplored compared with MAMBAC and MAXCOV, both of which have been evaluated in considerable detail (Beauchaine & Beauchaine, 2002; Cleland & Haslam, 1996; Cleland, Rothschild, & Haslam, 2000; Haslam & Cleland, 1996, 2002; Meehl, 1995b; Meehl & Yonce, 1994, 1996).

Winnowing the Item Pool and Evaluating Consistency Tests

As we noted earlier, even when a latent construct is distributed discretely, some markers are more precise than others and are therefore more efficient in differentiating taxon group members from nontaxon group members. This is true regardless of how carefully one chooses among candidate indicators. Given the likelihood of missing underlying taxa when inefficient indicators are used, systematic screening of each candidate variable is required to ensure that failure to find a taxon is not a false negative outcome. Accordingly, we have advocated that a two-step process initially proposed by Meehl (1995a, 2001a; see also Waller et al., 1996) be conducted to winnow an initial set of potential indicators. This includes preliminary screening of all candidates using MAMBAC. If these MAMBAC analyses suggest the possibility of discrete latent structure among a subset of indicators, only that subset is subjected to further analyses using MAXCOV and/or MAXEIG (Beauchaine, 2003b). This procedure filters the initial set of candidate indicators into a smaller number that are more efficient at differentiating between groups. Our recommendation is to plot all pairwise combinations of MAMBAC functions in a similar fashion to that appearing in Figure 23.8. This matrix can then be scanned for indications of taxonic structure. If nearly all of the MAMBAC functions are dish-shaped, then no further analyses are indicated, as there is no evidence of taxonic structure. If a taxon is present, the most likely scenario is that some MAMBAC plots will be hill-shaped, whereas others will be dish-shaped. The advantage of arranging all pairwise MAMBAC functions as in Figure 23.8 is that specific

variables that do not mark the latent taxon can be identified rather easily because most of the MAMBAC plots in the rows and columns representing such variables will be dish-shaped. These variables can then be eliminated from the indicator pool.

Next, remaining indicators are subjected to further analyses using MAXCOV or MAXEIG, which are used as *consistency tests* for judging the veracity of taxonic hypotheses. The term consistency test refers to comparisons of several parameters describing the latent distribution of a taxon and its complement. For example, if 10 potential indicators of melancholic depression are winnowed down to 6 through initial MAMBAC analyses, the first consistency test is to examine all base rate estimates from the MAMBAC runs. Six indicators produce

$$2 \binom{k}{2}$$

, or 30 combinations of variables for analysis (see Figure 23.8). If there is a latent taxon present, then valid indicators should produce consistent estimates of the taxon base rate across variable pairings. If most base rate estimates fall within a small range, then the taxonic hypothesis is conditionally supported and the indicators are subjected to MAXCOV and/or MAXEIG analyses. With 6 indicators, there are

$$i \times \frac{(i-1)!}{(i-3)!2!}$$

or 60 three-way combinations of variables available for MAXCOV analysis, each of which produces estimates of the base rate, the taxon and complement class means, and the hitmax value, among other latent parameters. Again, only when the preponderance of within-parameter estimates converge on single values is the taxonic hypothesis supported. Evidence also suggests that a goodness-of-fit index (Jöreskog & Sörbom, 2001) above .90 indicates taxonic structure (Waller & Meehl, 1998).

Type I and Type II Errors

As with any statistical approach, taxometric analyses can yield (a) spurious positive findings, thereby identifying taxa that do not exist (Type I errors) or (b) false negative findings, or failures to identify taxa that do exist (Type II errors). To date, more emphasis has been placed on avoid-

ing the former than on avoiding the latter. As we have noted elsewhere, however, Type II errors may be more common than Type I errors in taxometrics research given the requirements of high measurement precision and indicator validity outlined earlier. We now outline considerations for avoiding both types of error.

Pseudotaxonicity

The winnowing of candidate indicators into subsets that are more efficient at identifying a putative latent taxon has been criticized by some authors as a means of stacking the deck in favor of confirming taxonic hypotheses (Widiger, 2001), or of committing Type I errors. Part of this concern arises from the observation that attitudes and beliefs are particularly susceptible to dichotomous thought processes, a notion with considerable support in the literature on decision making (e.g., Simon, Pham, Le, & Holyoak, 2001). Thus, taxometric analyses of such variables could be reflecting the cognitive sets of raters rather than an objective underlying taxon. In an experimental paradigm in which we manipulated raters' implicit beliefs about a construct as dimensional versus dichotomous, we recently demonstrated that taxonic distributions can be readily imparted in Likert-type ratings (Beauchaine & Waters, 2003). Given that most taxometric studies have used such data exclusively, Widiger's concern may be justified. Indeed, rating scales reliably elicit positive and negative response biases (e.g., Macmillan & Creelman, 1990; Rajendar, 1996) and halo effects (e.g., Saal, Downey, & Lahey, 1980), both of which might result in artifactual taxonic structure, sometimes referred to as *pseudotaxonicity* (Beauchaine & Waters, 2003; Brown, 2001; Meehl, 1996). It is also well-known that human beings have natural tendencies to categorize continua (see Malt, 1993; Rosch & Lloyd, 1978; Smith, 1995) and to classify based on preexisting beliefs (see Cantor & Gero, 1986; Cantor & Mischel, 1979; Flanagan & Blashfield, 2002; Semin & Rosch, 1981).

All of these findings suggest due caution in interpreting latent taxonic structure that emerges from strictly rating scale data. However, when appropriate indicators are used that represent multiple levels of analysis including carefully chosen endophenotypes, and when multiple consistency tests converge on similar latent parameter estimates across CCK procedures (Meehl, 1995a; Waller & Meehl, 1998), the Type I error rate is exceedingly low. In fact, the prior probability of multiple objective indicators drawn from several levels of analysis converging on consistent base rate, hitmax, taxon group mean, and complement class mean estimates across 30 MAMBAC and 60 MAXCOV

runs approaches zero if there is no latent taxon present in a multivariate data set.

Sampling

A second potential source of artifactual taxonic structure and resulting Type I error comes from inappropriate sampling procedures. For example, if a clinical sample of individuals is recruited and their psychiatric impairment scores on a construct of interest are admixed with those of participants from a normative control group, then confirmation of a taxonic hypothesis is tautological. In fact, it would be surprising indeed if no taxon was detected among participants recruited with a bimodal distribution of symptoms. Unfortunately, evidence for taxonic structure among eating disorders derives directly from such sampling practices. Two separate studies have now appeared in which taxometric analyses were conducted on eating disorder symptoms among women diagnosed with anorexia, bulimia, or binge eating disorder. In both cases, these psychiatric groups were combined with nonclinical control groups, and MAMBAC and MAXCOV analyses were performed on symptoms in the admixed sample (Gleaves, Lowe, Green, Cororve, & Williams, 2000; Williamson et al., 2002). Not surprisingly, evidence for discrete latent structure among eating disorders was found. The proper sampling procedure for testing taxonic hypotheses is to recruit across a wide range of symptoms for a given disorder, with a *representative* proportion of participants at each symptom level. In a recent study in which representative sampling procedures were followed, no evidence for latent taxonic structure among eating disorders emerged (Tylka & Subich, 2003). Although some authors have suggested that the usefulness of taxometric methods depends on their ability to differentiate true taxa from pseudotaxa (Waldman & Lilienfeld, 2001), no statistical procedure is immune to sampling biases, and holding taxometric methods to a higher standard than other inferential statistics is almost certainly unjustified (Meehl, 1995a).

Proving the Null

Although a number of researchers have issued warnings about the potential for committing Type I errors in taxometrics research (Beauchaine & Waters, 2003; M. B. Miller, 1996; A. Ruscio & Ruscio, 2002; J. Ruscio & Ruscio, 2004a, 2004b; Widiger, 2001), few have addressed the possibility of committing Type II errors, or concluding that constructs are dimensionally distributed when they are in fact taxonic. We consider this to be a serious omission from the discourse on taxometric methods and propose that Type II errors may in fact be more likely

than Type I errors. This is because many researchers equate negative findings from taxometric analyses with proof of continuous latent structure. However, because taxometric procedures are structure seeking, the effective null hypothesis is that the analyzed trait or disorder is distributed continuously, and the alternative hypothesis is that it is distributed categorically. Thus, CCKs do not identify continua; they identify taxa. This maps directly onto both null hypothesis significance testing and signal detection theory. When there is inadequate separation of the null or noise distribution (complement class) from the alternative or signal distribution (taxon), no effect will be found even if one exists. Moreover, in the two-group case using null hypothesis significance testing, the null hypothesis is that both sets of scores derive from one distribution. The alternative hypothesis is that they derive from two discrete distributions. This is completely analogous to the multivariate case addressed by CCKs. Concluding that a negative result from a taxometric procedure suggests a continuous distribution is therefore tantamount to proving the null and should be avoided. Consider the case of a latent taxon group and complement class with a mean separation of $d = .80$ on all indicators. Despite the fact that this represents a large effect size in psychological research, CCKs cannot resolve the groups. Yet, if one concluded based on the results of a taxometric analysis that the latent distribution was continuous, one would be wrong. This is particularly important when we consider that the data sources commonly subjected to taxometric analyses are imprecise (see earlier discussion). Many taxometrics studies are therefore underpowered due to both low measurement precision and the large effect sizes required for a taxon to be detected. It is always possible that more precise measures could yield a latent taxon in future investigations.

Interpreting null outcomes as evidence of continua is particularly problematic when insufficient attention is paid to indicator validity. For example, in their otherwise impressive assessment of the latent structure of attachment, Fraley and Spieker (2003) used all potential indicators that correlated .20 or higher with a given attachment security subtype in their taxometric analyses, assuming implicitly that all such indicators were equally valid markers of any existing latent taxon. In analyses of the avoidant subtype, 12 indicators met this criterion, which were subjected to all possible combinations of MAXCOV analyses ($n = 660$). Based on their results, Fraley and Spieker concluded that avoidant attachment is distributed continuously. Although this may be the correct conclusion, the taxonic hypothesis was probably not put to a

strong test because it is a priori unlikely that all 12 indicators could mark a group of avoidant children with sufficient precision for MAXCOV to detect a discrete latent distribution (see earlier discussion). For these reasons, we recommend that researchers exercise prudence in interpreting null findings.

IMPLICATIONS FOR DEVELOPMENTAL PSYCHOPATHOLOGY

In describing taxometric methods, we have thus far outlined several examples in which CCKs have been applied to questions about the latent structure of psychopathology. Among these examples, we have presented evidence of discrete latent structure for schizotypy, endogenous depression, and extreme antisocial behavior. Each of these traits has been demonstrated as taxonic in multiple studies by different research labs. This provides some degree of confidence that the findings reported are not spurious. In contrast, evidence for an eating disorder taxon appears to be an artifact of inappropriate sampling procedures.

Although we do not intend to review all taxometrics studies conducted to date, it is instructive to provide a partial list of additional traits and disorders for which evidence of discrete latent structure has been published (for reviews, see Haslam, 2003; Haslam & Kim, 2002). This serves the dual functions of communicating the scope of the current literature and providing insights into traits that might also be examined (or further examined) in developmental samples, whether child, adolescent, or adult. In addition to the traits mentioned previously, evidence of latent taxonic structure has been reported for dementia (Golden, 1982), dissociative experiences (Waller et al., 1996; Waller & Ross, 1997), infant behavioral reactivity (Woodward, Lenzenweger, Kagan, Snidman, & Arcus, 2000), hypnotic susceptibility (Oakman & Woody, 1996), self-monitoring (Gangestad & Snyder, 1985), sexual orientation (Gangestad, Bailey, & Martin, 2000), vulnerability to depression (Strong, Brown, Kahler, Lloyd-Richardson, & Niaura, 2004), and Type A behavior patterns (Strube, 1989). Among these findings, only the dissociative experiences taxon has been replicated in independent samples, and only the infant behavioral reactivity taxon was derived using objective, continuous indicators. Thus, even though the use of CCKs has become increasingly popular, imprecise measures continue to predominate in taxometric analyses, despite the caveats outlined earlier.

We now turn our attention to questions of specific concern to developmental psychopathologists that CCKs are well suited to address. We begin with a detailed account

of the role that taxometric methods have already played in the identification of genetic vulnerability for Schizophrenia among children and adolescents. These findings have significant implications for development of the next generation of prevention programs. Moreover, research on the latent structure of schizotypy provides an exemplar for those seeking to conduct taxometrics studies in other areas. This is because Schizophrenia researchers have long recognized the importance of using precise endophenotypes to identify individuals at risk for the disorder. As we outline, this has led to remarkable advances in early detection of vulnerability to Schizophrenia spectrum disorders.

Identifying Children at Risk for Schizophrenia

Almost 40 years ago, long before the emergence of developmental psychopathology as a distinct discipline, Dawes and Meehl (1966) suggested that premorbid identification of individuals at risk for psychiatric disorders should be an urgent concern among psychopathology researchers because it is a necessary antecedent to prevention. It is therefore fitting that the most widely replicated finding in the taxometrics literature confirms Meehl's (1962) hypothesis that schizotypy is distributed as a discrete latent class that can be identified premorbidly. Through taxometric analyses of sustained visual attention, neuromotor performance, and intelligence measures, Erlenmeyer-Kimling et al. (1989) identified a schizotypy taxon group among the 7- to 12-year-old offspring of parents with Schizophrenia. Although the base rate of schizotypy is about 5% in the general population (Blanchard et al., 2000; Golden & Meehl, 1979; Korfine & Lenzenweger, 1995; Lenzenweger, 1999; Lenzenweger & Korfine, 1992), 47% of children with an afflicted parent were members of the schizotypy taxon group, compared with the expected 4% of controls. Moreover, 43% of the schizotypy taxon group were either hospitalized or had received significant treatment by age 22 to 29. Similar findings were reported by Tyrka, Cannon, et al. (1995), who used behavioral data derived from school reports and psychiatric interviews to identify a schizotypy taxon group among the 10- to 19-year-old offspring of mothers with Schizophrenia. The base rate of the taxon (48%) was almost identical to that found by Erlenmeyer-Kimling et al. Furthermore, 40% of those in the taxon group were diagnosed with a Schizophrenia spectrum disorder 24 to 27 years later. Thus, taxometric analyses of selected behavioral and endophenotypic markers can provide significantly improved prediction of clinical outcomes across considerable periods of time.

The implications of these findings for prevention can hardly be overstated. Targeting all children of parents with Schizophrenia for prevention is woefully inefficient because only 10% to 15% will go on to develop a Schizophrenia spectrum disorder (see Cornblatt, Obuchowski, Roberts, Pollack, & Erlenmeyer-Kimling, 1999). In the studies just reported, however, taxon group members were at 3 to 4 times this level of risk. More reliable identification of risk makes prevention programs much more plausible (Cornblatt, 2001). Furthermore, recent developments in the identification of precise endophenotypes in at-risk children, including impaired attention (Cornblatt & Malhotra, 2001), saccadic intrusions in smooth pursuit eye tracking (Ross, 2003), and spatial working memory deficits (Glahn et al., 2003), may allow for premorbid identification of vulnerability at even younger ages. In theory, the earlier an environmentally focused intervention is implemented, the more likely it is to alter the trajectory toward Schizophrenia because accumulated environmental risk contributes to the expression of genetic vulnerability (see Goldsmith, Gottesman, & Lemery, 1997; Gottesman & Gould, 2003; Rutter et al., 1997). Indeed, Raine, Mellinger, Liu, Venables, and Mednick (2003) reported that a very nonspecific environmental enrichment intervention for 3- to 5-year-olds reduced rates of schizotypal personality at age 23. This finding is especially impressive given that they did not target children specifically at risk for Schizophrenia, nor was their intervention tailored for reducing Schizophrenia risk. Rather, it was a blanket intervention including nutritional enhancement, child social skills training, and teacher instruction in behavioral management.

Evidence suggests that more focused interventions targeting children at particularly high risk could improve outcome and course, and perhaps even delay and in some cases prevent the onset of Schizophrenia (see Cornblatt, 2001; Cornblatt et al., 1999). Such prevention programs might include psychosocial components aimed at reducing expressed emotion, which is observed at high levels in families of at-risk children and exerts strong influences on both course and prognosis (Falloon et al., 1985; Hamilton, Asarnow, & Tompson, 1999; Hogarty et al., 1991). Although not without ethical complications (Cornblatt, Lencz, & Kane, 2001), prevention programs might also include a pharmacological component in extremely high-risk cases. McGorry et al. (2002) recently demonstrated that a low dose of risperidone (1 to 2 mg/day) substantially reduced the emergence of first-episode psychosis in high-risk patients who had a positive family history and incipient but subthreshold symptoms. Survival analyses revealed that patients who took risperidone and partici-

pated in cognitive behavioral therapy were 95% psychosis free 3 years later, compared with 30% of patients who received a typical needs-based intervention, and 40% of patients who did not adhere to the risperidone treatment. These findings are especially important given evidence that early and successful treatment of psychosis is associated with a better long-term prognosis (see Cornblatt et al., 2001).

Early Identification of Other High-Risk Traits

A second high-risk trait that has been identified as taxonic in very young children is behavioral reactivity. In a taxometric study of the responses of 599 4-month-old infants to a series of visual, auditory, and olfactory stimuli, Woodward et al. (2000) identified an extremely reactive taxon group who engaged in more arching, crying, hyperextension, and leg movements during stimulus presentations than other infants. Moreover, the 10% of infants who belonged to the taxon group scored high on measures of behavioral inhibition at age 4½, suggesting a potential vulnerability to later anxiety and depressive disorders (Kagan, 1994). Although these findings followed from a well-articulated theory, and although continuous and objective indicators were used in taxometric analyses with a large sample, future replications will be important in establishing the validity of the behaviorally reactive taxon group, as will follow-up studies specifying long-term outcomes for group members. Interestingly, the 10% base rate obtained by Woodward et al. is very close to the base rate observed among young adults by Beach and Amir (2003) in their taxometric study of involuntary defeat syndrome, a construct similar to endogenous depression. Given the high degree of overlap between depression and anxiety, and given findings that behavioral inhibition and anxiety both precede and predict later depression (Caspi, Moffitt, Newman, & Silva, 1996; Cole, Peeke, Martin, Truglio, & Seroczynski, 1998), the question arises as to whether behaviorally reactive taxon group members are at particularly high risk for later mood disorders. The value of identifying the behavioral reactivity taxon will be determined when more is known about its predictive potential.

Finally, as we reviewed in previous sections, Skilling, Quinsey, et al. (2001) reported evidence for an antisocial behavior taxon in a large community sample of fourth-through eighth-grade boys. This followed three studies identifying potentially similar taxon groups among substance abusing and incarcerated adult males (Ayers et al., 1999; Harris et al., 1994; Skilling, Harris, et al., 2001; Skilling, Quinsey, et al., 2001). Unfortunately, because

sampling procedures differed across studies, base rate estimates cannot be compared. Nevertheless, the 8% base rate in the community sample is a plausible figure for those at risk for continued delinquency into adolescence and adulthood.

As we also noted earlier, although each of the studies used primarily rating scale indicators, taxometric analyses of a number of potential endophenotypes may allow for more precise specification of a high-risk taxon group at younger ages. These markers include the P300 event-related brain potential (Patrick et al., 2005), sympathetic nervous system-linked cardiac insensitivity to reward (e.g., Beauchaine et al., 2001), attenuated electrodermal responding (e.g., Fowles, 2000), and reduced central nervous system striatal activation during response inhibition tasks (e.g., Durston et al., 2003; Vaidya et al., 1998).⁷ Candidate behavioral markers include manipulativeness, callousness, and lack of empathy, each of which has been tied to severe conduct problems and psychopathy (e.g., Barry et al., 2000; Frick, Cornell, Barry, Bodin, & Dane, 2003). As in the case of schizotypy, early identification of risk can facilitate targeted interventions with young at-risk children, who are known to respond better to prevention and intervention programs for conduct problems than older children and adolescents with established patterns of delinquent behavior (see Dishion & Patterson, 1992; Ruma et al., 1996; Webster-Stratton & Hammond, 1997; Webster-Stratton, Reid, & Hammond, 2002). Recent findings suggest that very early intervention may even alter endophenotypic markers of impulsivity and aggression that were once thought to reflect stable traits. Raine et al. (2001) reported that a prevention program for 3- to 5-year-old children including child social skills training, behavioral management instruction for teachers, and weekly counseling sessions for parents resulted in a 61% increase in electrodermal activity in participant children 6 to 8 years later, compared with controls who received no treat-

⁷ Although both the Durston et al. (2003) and Vaidya et al. (1998) studies were framed as comparisons of ADHD participants with controls, those with Oppositional Defiant Disorder and CD were not excluded. Given both theoretical and empirical evidence linking delinquency to deficient central nervous system reward processing (see Beauchaine, 2001; Beauchaine et al., 2001), and given the high degree of overlap between conduct problems and ADHD in clinical samples (R. G. Klein et al., 1997; Lynam, 1996, 1998), striatal dysfunction may in part give rise to the latent vulnerability underlying both behavioral syndromes. It should therefore be considered a potential endophenotype.

ment. Thus, long-term changes in a marker that has repeatedly been associated with impulsive aggression resulted from a straightforward preschool intervention. These findings are particularly encouraging because they suggest a potential mechanism through which early intervention may exert its effects.

Drawing Boundaries between Subtypes of Disorders

Although not necessarily developmental in nature, taxometrics can also contribute to defining boundaries between subtypes of psychiatric disorders. In previous sections, we outlined the role that taxometric studies have already played in differentiating between subtypes of depression. These studies have identified a discretely distributed melancholic subgroup in both adolescent and adult samples (Ambrosini et al., 2002; Beach & Amir, 2003; Grove et al., 1987; Haslam & Beck, 1994). It has been known for some time that melancholic symptoms are associated with nonsuppression of cortisol in response to dexamethasone challenge (Rush & Weissenburger, 1994). In turn, cortisol nonsuppression was recently shown to mark a 10-fold increase in suicide risk at 15-year follow-up among depressed patients (Coryell & Schlessner, 2001). Although no taxometric studies of depression have used biological markers, these findings suggest that the dexamethasone suppression test may be a promising endophenotype for prospective identification of risk. Other possible endophenotypes include measures of sleep disturbance such as REM latency, which has also discriminated between melancholic and nonmelancholic depression subgroups (e.g., Rush, Giles, Schlessner, & Orsulak, 1997). In addition to the potential advantages of using endophenotypes such as HPA axis reactivity to identify vulnerability in younger children (Luby et al., 2003, 2004), replication of taxonomic findings using such markers might resolve the controversy surrounding the latent structure of depression described in footnote 6.

Taxometrics research might also elucidate boundaries between subtypes of ADHD, where debate continues over the distinctiveness of the *combined* type (ADHD/C), characterized by hyperactivity/impulsivity and inattention, and the *inattentive* type (ADHD/I), characterized primarily by inattention. Some authors have argued that the disorders are probably discrete (e.g., Milich, Balentine, & Lynam, 2001), whereas others have suggested that current data are inconclusive (Barkley, 2001; Hinshaw, 2001; Lahey, 2001). Evidence for discrete subtypes is derived from factor analyses that differentiate among symptoms and from cluster analyses that differentiate among chil-

dren based on disparities in symptoms. As described earlier in this chapter, these methods are not well suited for evaluating the latent structure of psychopathology. Moreover, results have been somewhat inconsistent (Milich et al., 2001), and few studies have included markers that correlate specifically with ADHD/I. Among viable candidates is the construct *sluggish cognitive tempo* (SCT), which includes symptoms of lethargy, daydreaming, drowsiness, and hypoactivity (Carlson & Mann, 2002; Lahey, Carlson, & Frick, 1997). Although SCT items correlated specifically with ADHD/I in the *DSM-IV* field trials, they were dropped from the final criterion list because the workgroup sought a single set of inattentive items for both ADHD subtypes (Carlson & Mann, 2002; Frick et al., 1994). Yet, children with ADHD/I score higher on measures of SCT than other children with ADHD (McBurnett, Pfiffner, & Frick, 2001; Milich et al., 2001). Indices of SCT might therefore be useful in taxometric investigations that directly address the distinctiveness of ADHD/I and ADHD/C.

Additional symptoms that may differentiate between ADHD/I and ADHD/C include lower levels of externalizing behaviors and higher levels of anxiety, depression, and social withdrawal (Carlson & Mann, 2002). Such internalizing symptoms were more strongly associated with inattention than with impulsivity in the Multimodal Treatment of ADHD trial (Newcorn et al., 2001). Two final behavioral markers that might differentiate between ADHD subtypes are age of onset and age of referral, both of which occur earlier in ADHD/C than in ADHD/I (e.g., Faraone, Biederman, Weber, & Russell, 1998; Frick et al., 1994).

Research on the neurobiology of ADHD also suggests some potential endophenotypes for taxometric analyses. For example, several studies have revealed reduced urinary MHPG, a norepinephrine metabolite, among children with ADHD (e.g., Shekim, Dekirmenjian, Chapel, & Davis, 1982; Shekim et al., 1987). These MHPG deficiencies have been linked specifically with the biobehavioral substrates of impulsivity (see Beauchaine, 2001) and are therefore more likely to be associated with ADHD/C than ADHD/I. Consistent with this prediction, Kagan, Reznick, and Snidman (1987) found increased urinary MHPG in anxious children. Given the higher rates of anxiety among children with ADHD/I and SCT (Carlson & Mann, 2002; Hinshaw, 2002a), urinary MHPG may be a promising endophenotype for taxometric analyses assessing the latent structure of ADHD subtypes.

Yet another diagnostic conundrum that might be addressed with taxometric methods is whether Autistic

Disorder and Asperger's Disorder reflect discrete behavioral syndromes or fall along a continuum of severity. This question has received substantial attention in both the child psychopathology and developmental psychopathology literatures since Asperger's Disorder was added to the *DSM-IV*, but it has yet to be resolved (Volkmar, Klin, Schultz, Rubin, & Bronen, 2000). Criteria shared by both disorders include impaired social interaction, stereotyped behaviors, and restricted interests and activities. Autism includes additional delays in verbal communication and/or cognitive development, whereas Asperger's Disorder does not.

Some authors have concluded that Autistic Disorder and Asperger's Disorder are likely to be discrete (see Klin, 1994; Ozonoff, Rogers, & Pennington, 1991). This argument is based on different patterns of comorbidity across diagnostic groups (Ghaziuddin, Weidmer-Mikhail, & Ghaziuddin, 1998), differences in verbal and nonverbal communication skills (e.g., Klin, Volkmar, Sparrow, Cicchetti, & Roarke, 1995; Volkmar et al., 1994), and different concordance rates across disorders in the first-degree relatives of affected patients (Volkmar, Klin, & Pauls, 1998). However, each of these characteristics could be observed in groups that differ in severity due to an arbitrary dichotomization on a continuous dimension.

Proponents of a continuous Autism spectrum model point to similarities in clinical features (e.g., Eisenmajer et al., 1996), neuropsychological test performance (J. N. Miller & Ozonoff, 2000), and brain stem abnormalities (Bauman, 1996). However, none of these necessarily precludes latent discontinuities on other criteria. Additionally, Constantino and Todd (2003) recently advocated for a continuum model of severity based on the absence of bimodality in a distribution of Social Responsiveness Scale (Constantino, 2002) scores collected from a large sample. Yet, as we outlined earlier, this is probably the least powerful method for resolving discrete latent structure.

As stressed repeatedly by Meehl (e.g., 1995a, 2004), ontological questions such as these cannot be addressed without subjecting phenotypic and endophenotypic markers to taxometric analyses. Although many disorders lack indicators of sufficient validity to perform such analyses, this is not the case for Autism spectrum disorders, where a number of precise markers have been specified at several levels of analysis (see Akshoomoff, Pierce, & Courchesne, 2002; Dawson, Webb, et al., 2002; Klin, Jones, Schultz, Volkmar, & Cohen, 2002). In the social domain, infants with Autism direct their gaze toward others less frequently and orient to their names less often than controls, and adults attend less to the eyes of others

when observing social interactions (Klin et al., 2002; Osterling, Dawson, & Munson, 2002). At the psychophysiological level, children with Autism spectrum disorders exhibit attenuated event-related brain potentials when presented with familiar faces (Dawson, Carver, et al., 2002). Finally, children with Autism exhibit a number of brain chemical alterations (Friedman et al., 2003) and experience accelerated trajectories in brain growth between the ages of 2 and 4 (Courchesne et al., 2001); as outlined earlier, growth trajectories typically provide increased measurement precision over cross-sectional measures and may therefore be useful in taxometrics research. These are but a few examples of potential phenotypes and endophenotypes for Autism (see Dawson, Webb, et al., 2002). If taxometric studies suggest that subsets of these markers identify a discrete latent class, studies aimed at elucidating the differential etiological mechanisms of Autism and Asperger's Disorder will need to be pursued.

Specifying Equifinal and Multifinal Pathways to Psychopathology

As outlined earlier, equifinality refers to the processes through which multiple etiological pathways lead to an apparently single behavioral syndrome. Using our previous example, findings suggesting that ADHD can result from genetically mediated central dopamine dysfunction, structural insults to the central nervous system, and in utero exposure to drugs of abuse represent an example of equifinality. In contrast, multifinality refers to processes through which children who are at similar risk levels diverge toward disparate behavioral outcomes, only some of which are disordered (Cicchetti & Rogosch, 1996). For example, accumulating evidence suggests that children who are temperamentally impulsive fare poorly in terms of delinquency outcomes when raised in high-risk neighborhoods compared with similar children raised in low-risk neighborhoods (e.g., Lynam et al., 2000). Equifinality and multifinality imply that a full appreciation for heterogeneity in individual outcomes can be attained only through longitudinal assessment of interactions between child-specific variables (e.g., temperament) and environmental experiences (e.g., neighborhood context). Thus, specifying mechanisms of equifinality and multifinality requires that homogeneous subgroups of children who are at differential risk for psychopathology be followed throughout the natural course of development (Hinshaw, 2002b; Richters & Cicchetti, 1993).

For vulnerability traits that are discrete, taxometric methods provide a means of characterizing homogeneous subgroups for such follow-up studies. As described previously,

for example, Woodward et al. (2000) identified a discrete behavioral reactivity taxon comprising 10% of 4-month-old infants in a large sample. Four years later, members of this extremely reactive group scored high on measures of behavioral inhibition. These findings provide a unique opportunity to explore developmental outcomes among qualitatively distinct subgroups of children who are at differential risk for later internalizing disorders (see Kagan, 1997). Longitudinal follow-ups will provide for identification of environmental experiences in the home, school, and neighborhood that both mitigate and attenuate vulnerability to psychopathology. In addition to evaluating mechanisms for such multifinal outcomes, longitudinal follow-ups will also provide the opportunity to determine what sets of differential experiences result in similar outcomes for taxon and complement class members, thereby addressing questions of equifinality as well. For discrete vulnerability traits, well-designed taxometric analyses ensure that subgroups of children in such studies are not specified arbitrarily.

Specifying Etiologically Homogeneous Subgroups for Behavior Genetics Research

As we noted in the introduction to this chapter, most proponents of the search for endophenotypes in psychopathology research have expressed particular concern about the etiological heterogeneity of groups defined strictly by behavioral syndromes, due to the attenuating effect this has on estimates of genetic linkages and associations (Castellanos & Tannock, 2002; Cornblatt & Malhotra, 2001; Gottesman & Gould, 2003; Skuse, 2001). For example, although behavior genetics studies have repeatedly demonstrated heritability coefficients of about .80 for impulsive behavior (Cadoret, Leve, & Devor, 1997; Hinshaw, 2002a), both population- and family-based studies of two promising candidate genes, DAT1 and DRD4, suggest relatively low-risk values (e.g., LaHoste et al., 1996; Smalley et al., 1998). Although additional genes are clearly implicated in ADHD (Castellanos & Tannock, 2002; Swanson & Castellanos, 2002), part of the reason for low genetic associations is that the ADHD phenotype identifies an etiologically heterogeneous group whose symptoms arise from multiple equifinal causes, only some of which involve central dopamine dysfunction (see earlier discussion). To the extent that taxometric analyses performed on precise endophenotypes can identify more etiologically homogeneous subgroups for behavior genetics studies, advances in our understanding of gene-behavior relations will almost certainly be realized. This in turn will provide for early identification of genetic risk, earlier delivery of services, and longitudinal follow-ups of high-risk individuals. Thus, rather than focusing on fully developed dis-

orders in childhood, premorbid identification of risk will allow us to take full advantage of the strengths offered by a developmental psychopathology framework.

Identifying Person-Specific Moderators of Treatment Outcome

In intervention research, taxometric studies can also help to identify person-specific moderators of treatment outcome. A moderator is any variable present at baseline that discriminates between those who respond differentially to treatment (e.g., Hinshaw et al., 2000; Kraemer, Stice, Kazdin, Offord, & Kupfer, 2001; Kraemer, Wilson, Fairburn, & Agras, 2002). For discretely distributed traits, taxometrics can identify nonarbitrary groups for whom differential treatment response may be assessed. When moderating variables are found, they facilitate identification of processes that enhance or diminish the impact of an intervention in different groups (see Hinshaw, 2002b). For example, if a group of endogenous depressives, as identified through taxometric analyses of appropriate phenotypic and endophenotypic markers, responds less favorably to cognitive-behavioral therapy than their exogenous depressive counterparts, then we know more about the treatment of depression than we would have known had we not identified the person-specific moderator (endogenous depression). Moreover, we may be in a position to offer an alternative treatment that provides a comparative advantage.

In treatment-outcome research on conduct problems, a number of authors have called for identification of person-specific treatment moderators (Beauchaine et al., *in press*; Brestan & Eyberg, 1998; Nock, 2003). These calls have followed from recognition that fully one-third of children do not benefit from the most successful interventions (Webster-Stratton & Hammond, 1997; Webster-Stratton et al., 2002), yet we currently know very little about child-specific predictors of treatment response. In future research, it will be of interest to see whether the severe antisocial/psychopathy taxon can be detected in young children, and if so, whether children in the taxon group respond differentially to treatment. Such a finding would enable treatment providers to identify children who are less likely to be treatment responders before initiating an intervention. This information could be invaluable for formulating more targeted interventions for specific subgroups of children who are not benefiting from current approaches.

Informing Research on Comorbidity

Before offering specific recommendations for future research, we would also like to comment on the utility of

taxometrics for comorbidity research. Several authors have recently expressed enthusiasm for the potential role that taxometric methods might play in disentangling different sources of comorbidity (Meehl, 2001a; J. Ruscio & Ruscio, 2004a; Waldman & Lilienfeld, 2001). For example, suppose, for the sake of argument, that I subscribe to the theory that both the schizotypy taxon and the dissociative experiences taxon are identifying the same latent class using different indicators. In other words, dissociative experiences are simply a marker of schizotypy. Given approximate population base rates of around 5% for each taxon, and given some conceptual overlap in criteria, such an argument might be plausible. This hypothesis suggests that any apparent comorbidity is artifactual (D. N. Klein & Riso, 1993), because the two traits are actually identifying the same group. If this is the case, error-free taxometric analyses of both sets of indicators would yield perfect agreement in a 2×2 contingency table, classifying 5% of individuals into the taxon group and 95% of individuals into the complement class (J. Ruscio & Ruscio, 2004a). In contrast, suppose my colleague believes that the taxa are independent, in which case, the number of individuals assigned to the taxon by analyses of both sets of indicators should equal the product of the base rates ($.05 \times .05 = .0025$). Again, this assumes error-free classification.

Unfortunately, Bayes's theorem dictates that considerable error will be observed in the classification of any low base rate phenomenon (Baldessarini, Finklestein, & Arana, 1983), regardless of the approach to classification that is used. Accordingly, Monte Carlo simulations of the MAXCOV procedure in particular suggest that under low base rate conditions that are likely to face psychopathology researchers, the procedure is quite effective at detecting latent taxa but yields significant false-positive rates when classifying individuals into groups (Beauchaine & Beauchaine, 2002). For example, at a base rate of 5% using five indicators, a sample size of 300, an effect size of 1.25, and within-group correlations of .30, MAXCOV correctly classifies about 65% of individuals, with a false-positive rate of about 30% and a false-negative rate of about 10%. Thus, even if my colleague is correct in suggesting that schizotypy and dissociative experiences are independent, taxometric analyses with different sets of indicators will place roughly 10% ($.30 \times .30 = .09$) of individuals into the same taxon. Note that this is actually double the 5% base rate observed in both populations. This would lead to the erroneous conclusion that the two disorders are etiologically related (see J. Ruscio & Ruscio, 2004a), an incorrect interpretation that neither of us

hypothesized! Although other potential inferential errors could be described, this example alone tempers our enthusiasm for the utility of taxometrics in clarifying questions of comorbidity. In samples where base rates are higher, classification errors are far less common, and these limitations do not apply.

FUTURE DIRECTIONS

To date, CCKs have been used quite sparingly by developmental psychopathologists, yet their popularity continues to increase in other areas of psychopathology research. Although longitudinal taxometric studies remain exceedingly rare (for an exception, see Tyrka, Haslam, et al., 1995), several authors have begun to consider the developmental sequelae of members of high-risk taxon groups (Erlenmeyer-Kimling et al., 1989; Tyrka, Cannon, et al., 1995; Woodward et al., 2000). Taxometric analyses of antisocial traits have also been conducted in separate samples spanning middle school through adulthood (Ayers et al., 1999; Harris et al., 1994; Skilling, Harris, et al., 2001; Skilling, Quinsey, et al., 2001). Similarly, taxometric analyses of melancholic depression have now been conducted among adolescents as well as adults (Ambrosini et al., 2002; Beach & Amir, 2003; Grove et al., 1987; Haslam & Beck, 1994). These research efforts are encouraging given the advantages of person-centered techniques to identify heterogeneous longitudinal trajectories in behavioral maladaptation. Further efforts to specify the developmental sequelae of individuals afflicted with discretely distributed psychopathological traits will almost certainly identify specific mechanisms of equifinality and multifinality that produce diverse adjustment outcomes.

Consistent with these objectives, the most important future application of taxometric methods lies in identifying latent vulnerability traits that place children at significant risk for later psychopathology. Using the example of schizotypy, we described how taxometric analyses of carefully chosen endophenotypes have provided a three- to fourfold increase in our ability to predict later Schizophrenia among children with an affected parent. Early identification can in turn lead to targeted prevention programs designed to mitigate environmental risk before overt expression of the disorder. Although the research is in early stages, premorbid identification of vulnerability for both severe antisocial behavior and anxiety/depressive disorders may also be possible. If this potential is to be realized, researchers must continue to search for promising endophenotypes that mark latent vulnerabilities with greater precision than rating scale measures.

Furthermore, future research must be conducted with more careful attention to indicator validity. In other words, variables must be chosen for analysis based on strong theory regarding the latent trait they are assumed to mark (Beauchaine & Waters, 2003; Lenzenweger, 2004; Meehl, 1999; Waters & Beauchaine, 2003). The most common approach to taxometrics currently used is to extract all symptoms of a psychiatric disorder from a large data set of convenience and subject the entire set to multiple CCK algorithms. Often, this means that the only variables used are Likert-type ratings of psychopathology, with little or no attention to core versus peripheral symptoms of the underlying vulnerability trait. This shotgun approach is unlikely to be fruitful in future research for several reasons. First, most if not all current criterion lists of disorders in the *DSM-IV-TR* do not map onto a single vulnerability trait. For example, criteria for ADHD include inattentiveness, hyperactivity, and impulsivity items. Although there is currently no evidence of latent taxa for any of these traits, subjecting all ADHD symptoms to taxometric analyses would almost surely obscure any such taxon if it existed given that inattention and impulsivity are separable behavioral traits (Milich et al., 2001). For this reason, *DSM-IV-TR* criterion lists cannot be assumed to offer a proper starting point for taxonomic searches.

Consider the case of schizotypy. As outlined earlier, Meehl (1962) offered an elaborate theory of Schizophrenia vulnerability well before he invented most of his taxometric algorithms. This theory included a set of core symptoms that Meehl believed were markers of a single latent vulnerability to Schizophrenia. These symptoms, including interpersonal aversiveness, ambivalence, cognitive slippage, and anhedonia, did not map directly onto the criteria of Schizophrenia of the day, nor do they map directly onto current criteria for the disorder. Given this, subjecting all symptoms of Schizophrenia to a taxometric analysis would almost certainly result in a false negative outcome when searching for discrete latent structure, even though schizotypy is the most well-replicated taxonomic psychopathology trait yet identified (Blanchard et al., 2000; Erlenmeyer-Kimling et al., 1989; Golden & Meehl, 1979; Horan et al., 2004; Korfine & Lenzenweger, 1995; Lenzenweger, 1999; Lenzenweger & Korfine, 1992, 1995; Tyrka, Cannon, et al., 1995; Tyrka, Haslam, et al., 1995). A similar argument can be advanced for dissociation, a trait that is also distributed discretely (Waller et al., 1996; Waller & Ross, 1997) but does not map onto any specific psychiatric disorder.

These examples illustrate the importance of theoretically guided taxometrics research, where candidate indicators are identified before data collection and are measured

with as much precision as possible, preferably with at least some laboratory measures. When only psychometric data are used in taxometrics research, it is difficult to surmise the extent to which rater biases, halo effects, response biases, and/or low measurement precision are impacting one's results (see Beauchaine & Waters, 2003; Lenzenweger, 2004). Because most laboratory markers are both more precise than psychometric measures and are indexed on ratio scales, they are particularly well suited for taxometric analyses when chosen carefully.

To date, the predominant approach to dealing with measurement imprecision has been to develop ad hoc and ancillary techniques aimed at resolving discrete latent structure with suboptimal data. These include special procedures for accommodating dichotomous indicators (Golden, 1982, 1991), simulation techniques for resolving discrete latent structure with skewed indicators, and similar methods aimed at establishing the suitability of data for taxometric analyses (J. Ruscio & Ruscio, 2004a, 2004b). Although many of these methods are ingenious, they are almost never ideal solutions to the problems they address (see, e.g., Footnote 6). In future studies, developmental psychopathologists and other researchers will benefit from careful selection of highly precise indicators. There are probably no putative taxa for which dichotomous measures cannot be avoided. Moreover, unpublished data from our lab suggest that skewed indicators are far less likely to produce spurious taxonomic outcomes if they are continuous rather than discretely anchored.

These issues are not trivial. Ongoing arguments and inconsistencies in the adult psychopathology literature over the latent structure of both endogenous depression and psychopathy derive in part from issues of measurement imprecision and skew (Beach & Amir, 2003; Harris et al., 1994; Marcus, John, & Edens, 2004; J. Ruscio, Ruscio, & Keane, 2004). These controversies will probably never be resolved definitively without including more precise indicators of putative taxonomic constructs, preferably from psychophysiological cognitive, neurologic, and other levels of analysis, as originally advocated by Meehl (1995a, 2001b).

Developmental psychopathologists have long recognized the importance of addressing individual patterns of adaptation and maladaptation from multiple levels of analysis, including behavioral, physiological, and genetic, among others (Cicchetti & Dawson, 2002). Many developmental psychopathologists also reject the reification of diagnostic classes, preferring instead to focus on interactions between vulnerability traits and environmental experiences in shaping behavior and psychological adjustment. We are therefore perplexed by the omission of taxometrics from the

armamentarium of methodological techniques used by researchers in the field. Yet, we are optimistic that this will soon change. The potential of taxometrics to identify individuals at especially high risk for future psychopathology is simply too consistent with developmental psychopathology objectives for the techniques to remain unused. Furthermore, developmental psychopathologists are well positioned to make significant contributions to taxometrics research given the strong role of theory in their conceptualizations of mental disorders and behavioral adjustment. These emphases make it likely that developmental psychopathologists will conduct theoretically informed taxometric analyses toward identifying young children at particular risk for behavioral maladaptation.

As we continue to conduct taxometric research with younger samples, it will be particularly important to follow the same individuals over extended periods of time. As the schizotypy literature demonstrates, the greatest value of identifying latent vulnerabilities lies in prediction of future outcomes for group members. Specifying and predicting trajectories in behavioral adaptation and maladaptation have been the objectives of developmental psychopathology since its inception, and they remain so today (Rutter & Sroufe, 2000; Sroufe & Rutter, 1984). The taxometric methods of Meehl and his colleagues offer an as yet underutilized tool to aid in achieving these goals.

INTRODUCTION

According to the World Health Organization (2003), there are 450 million people worldwide affected by mental or behavioral problems at any one time. In the United States alone, the National Institutes of Mental Health (2001) estimate that 22.1% of Americans ages 18 and older suffer from a diagnosable mental disorder in a given year, which translates into approximately 44.3 million people. The consequences of having a mental disorder can be severe. For example, persons with mental disorders are often subjected to social isolation and have a poor quality of life. Furthermore, mental disorders account for 4 of the top 10 causes of disability, and persons with mental disorders have an increased risk for health problems and increased rates of mortality.

The numbers are staggering, and most people would agree that it is better to prevent the emergence of mental disorders and prevent suffering rather than waiting for a disorder to develop and then offer treatment. The prevention of mental and substance abuse disorders is not an easy task, however, and requires a complex understanding of both typical and atypical development, a strong underlying theory guiding preventive efforts, and a solid understanding of the sequential steps required to develop effective prevention programs.

The overarching goal of this chapter is to elaborate a developmental psychopathology approach to prevention science. In the first part of the chapter, we review basic research on normal and abnormal development and developmental psychopathology and articulate its integral relation to preventive interventions. As theory informs practice, practice also informs theory. Accordingly, we go on to describe how results from preventive intervention trials are uniquely able to serve as tests of developmental theory. "Prevention" is a widely, and often misused, term. We offer a brief history of the terminology associated with prevention and describe the prevention research cycle that takes into account the planned, sequential steps necessary to develop strong prevention programs that have the opportunity to promote the best outcomes as well as provide a wealth of information for developmental theory. We also discuss the interface of developmental psychopathology, epidemiology, and public health as it relates to prevention. Numerous prevention programs and outcomes examples are offered from

large-scale prevention trials in Baltimore, Maryland, as well as prevention programs targeted for the prevention of the negative sequelae of child maltreatment and maternal depressive disorder. The chapter concludes with directions for future research in preventive interventions.

THE IMPORTANCE OF UTILIZING AND TRANSLATING BASIC RESEARCH KNOWLEDGE ON NORMAL AND ABNORMAL DEVELOPMENT INTO PREVENTIVE INTERVENTIONS

The overarching and pragmatic goal of prevention science is to intervene in the course of development to reduce or eliminate the emergence of maladaptation and psychopathology. As such, a complex understanding of the course of normal development is essential to conceptualize how deviations in normal ontogenesis give rise to psychopathology. The discipline of developmental psychopathology, with its keen interest in the dialectic between normal and abnormal development, is thus uniquely poised to provide the theoretical foundations for prevention science.

An organizational perspective on development is central to developmental psychopathology (Cicchetti, 1993; Cicchetti & Schneider-Rosen, 1986; Cicchetti & Sroufe, 1978; Sroufe & Rutter, 1984). From this vantage point, development is conceptualized as a series of qualitative reorganizations within and among multiple domains of biological and psychological functioning. The individual successively advances from a state of diffuse undifferentiation to levels of increasingly differentiated and hierarchically organized biological and behavioral complexity (Werner & Kaplan, 1963). Across development, qualitative reorganizations among biological and psychological systems occur as the developing individual progressively is challenged with a series of stage-salient developmental tasks (e.g., physiological homeostasis, differentiation and regulation of affects, development of a secure attachment relationship, emergence of a positive and autonomous self, representational capacities, development of effective peer relationships, adaptation to school). How the individual strives to adapt to these developmental challenges influences the competence of functioning and the preparedness of the individual to successfully negotiate subsequent developmental tasks. Through progressive differentiation and hierarchic integration, the quality of adaptation at successive stages of development is incorporated into the reorganization of developmental systems. In this way, coherence of the individual is maintained over time (Sroufe, 1979). Nevertheless, there is both continuity and discontinuity

Preparation of this chapter was supported by grants from National Institutes of Mental Health and Drug Abuse to Drs. Ialongo and Cicchetti (Ialongo, MH066247, MH57005, DA11796; Cicchetti, MH 45027, MH54643, DA12903).

ity in the course of development. Competent adaptation at one period of development increases the likelihood of later competence, whereas incompetent adaptation promotes the probability of later incompetence. However, based on experience and the degree of success in meeting new developmental challenges, change in the quality of adaptation may occur (Cicchetti & Tucker, 1994).

From this perspective, maladaptation and psychopathology evolve from progressive liabilities in the developmental organization of biological and psychological systems, resulting in the undermining of the individual's efforts to adapt to experience effectively. The organizational developmental conceptualization appreciates that psychopathology can be differentiated both as a maladaptive extreme on a continuum of functioning and as a qualitatively distinct disorder discontinuous from normal functioning (Rutter & Garmezzy, 1983; Rutter & Sroufe, 2000).

This theoretical perspective directs prevention science to focus on the progressive organization of developmental competencies and incompetencies in the developmental course in order to structure preventive efforts. To effect change in the course of development and avert psychopathological outcomes, preventive interventions should be guided by an emphasis on promoting competence and reducing ineffective resolution of the stage-salient developmental tasks at different periods of development. In so doing, deflection of adaptation onto more adaptive developmental pathways may be achieved, thereby enhancing the individual's capacity for a greater likelihood of subsequent successful adaptation. Thus, attending to developmental competencies and liabilities rather than a sole focus on symptom reduction is crucial. Inherent in this developmental perspective is the value of early intervention, before developmental liabilities may become more consolidated. For those individuals at a particular developmental period who already are more vulnerable due to a compromised developmental organization, more intensive preventive efforts may be needed to promote access to more competent development pathways.

From the organizational perspective, it is clear that diverse pathways of development may unfold, as each developmental period presents new opportunities and challenges. Accordingly, the principles of multifinality and equifinality in developmental pathways are central to a developmental psychopathology conceptualization (Cicchetti & Rogosch, 1996). Multifinality implies that diverse and varied outcomes will occur in development despite a common early liability or risk condition. In turn, equifinality specifies that a common pathological outcome will eventuate from various origins and developmental routes. Prevention scientists thus realize that there are multiple pathways to disorder and dysfunction and that varied causal processes likely operate for

different individuals. Moreover, early vulnerability does not doom the individual to later disturbance, but rather, subsequent experience may promote the overcoming of early liabilities. Understanding pathways of resilient adaptation among individuals exposed to extreme risks and early adversity presents an important opportunity for prevention researchers (Luthar & Cicchetti, 2000). Identification of processes contributing to self-righting in the course of development for these individuals may be particularly valuable to incorporate into the design of preventive interventions (Cicchetti & Rogosch, 1997; Luthar & Cicchetti, 2000). Longitudinal research in developmental psychopathology is vital for delineating the varied developmental pathways that ensue for individuals experiencing high-risk conditions and for tracking the emergence of psychopathology. Such research is invaluable for delineating the mechanisms that translate risk and vulnerability into dysfunction (Rutter & Sroufe, 2000), forming a foundation on which to base preventive efforts.

A cornerstone of research in developmental psychopathology has been focused on risk and protective factors and their role in understanding psychopathological development. The dynamic interplay of risk and protective factors influences the developmental course by affecting the quality of the organization of biological and psychological systems as the individual develops. With the expansion of attention to risk factors, developmental psychopathology research has incorporated probabilistic, rather than deterministic, models of dysfunction. Moreover, consideration of individual risk factors in isolation is often insufficient to explain developmental variation. Rather, different risk factors frequently tend to co-occur, and the cumulative effects of multiple risk factors have been found to be particularly detrimental to competent development, thereby promoting the development of psychopathology (Deater-Deckard, Dodge, Bates, & Pettit, 1998; Rutter, 1979; Sameroff, Seifer, Barocas, Zax, & Greenspan, 1987). Thus, models elucidating the co-action of multiple risk factors are important, and risk factors at multiple levels of biological and psychological organization need to be considered (Cicchetti & Blender, 2004; Cicchetti & Dawson, 2002). In this regard, understanding the interplay between environmental and genetic risks is crucial, and models of gene-environment correlation and gene-environment interaction illustrate the complexity of risk mechanisms that operate to engender psychopathology. Additionally, research has demonstrated that specific risk factors may have greater salience in influencing the quality of developmental adaptation at different periods of the life course than at others (Kazdin, Kraemer, Kessler, Kupfer, & Offord, 1997). Moreover, different

risk factors may contribute probabilistically to the emergence of dysfunction, whereas other risk factors may be more influential in the maintenance of dysfunction or in subsequent relapse (Post, 1992).

In addition to risk factors, the other side of the equation involves a full appreciation of the protective factors that individuals experience across development. Protective factors may promote competence in their own right. Alternatively, some protective factors may be influential in safeguarding competent functioning, particularly in the context of specific risks. Research on protective factors is vitally important for identifying processes that contribute to resilient adaptation in the face of risk (Luthar, 2003; Luthar, Cicchetti, & Becker, 2000; Masten, 2001; Masten et al., 2004). Understanding the dynamic interplay of risk and protective factors is central to building models of prevention. Broadly speaking, prevention efforts are largely based on the goals of reducing the impact of identified risk factors as well as enhancing the complementary ameliorative effects of identified protective factors. Through increasing the relative balance of protective processes over risk factors, the potential for righting the developmental course, attaining adaptive developmental pathways, and reducing the emergence of psychopathology may be achieved (Cicchetti & Lynch, 1993; Cicchetti & Rizley, 1981).

PREVENTIVE INTERVENTION TRIALS AS TESTS OF DEVELOPMENTAL THEORY

The practical application of prevention science is clear. Effective prevention programs have the potential to significantly impact the developmental pathways for individuals and improve subsequent adjustment or reduce the emergence of future problems (Durlak, 1997). Although the quintessential goal of prevention science is to right the developmental course and prevent the emergence of psychopathology, the results of prevention trials also have important implications for developmental theory by providing a wealth of information about the developmental processes of typical and atypical development (Cicchetti & Hinshaw, 2002; Cicchetti & Toth, 1991, 1992; Hinshaw, 2002; Kellam & Rebok, 1992). Developmental theory forms the foundation for the practice of prevention, and the practice of prevention needs to form a circular link back to theory to advance both the theory and resulting practice. Because prevention scientists are often, and understandably, most interested in the practical outcomes of a prevention program, the research design and implementation of the program are often not optimal for informing developmental theory. The following section describes

a conceptual and practical framework for designing prevention programs that are maximally informative to developmental theory.

A CONCEPTUAL FRAMEWORK FOR DEFINING RISK IN THE CONTEXT OF DESIGNING PREVENTIVE INTERVENTIONS

Prevention scientists attempt to reduce the impact of identified risk factors, but the term "risk factor" has not always been consistently applied in research and policy (Kraemer et al., 1997). A risk factor has been defined as a measurable characteristic of each subject in a specified population that precedes the outcome of interest and divides the population into two groups: a high- and low-risk group (Kazdin et al., 1997; Kraemer et al., 1997). According to Kraemer et al., the subject does not necessarily have to be an individual person, but could be a family, school, community, or other unit of interest. Furthermore, the characteristic may be on the individual level (e.g., gender, size of school) or contextual level (e.g., family context, location of school). Overall, the probability of the outcome must be higher in the high-risk group than in the low-risk group (Kraemer et al., 1997) for a characteristic to be considered a potential risk factor. However, once this significant association is established between the risk factor and the outcome, researchers need to consider the clinical significance of the risk factor. According to Jacobi, Hayward, de Zwaan, Kraemer, and Agras (2004), clinical significance can be determined by understanding the magnitude or potency of the risk factor. Potency has been defined as the ability of the risk factor to achieve maximal discrepancy for dichotomizing the population into high- and low-risk groups (Kraemer et al., 1997). Potency can be expressed by a variety of summary measures including odds ratios, risk ratios, relative risk, and attributable risk.

The population and outcome of interest must be well defined before evaluation of risk factors and before the typology of risk factors can be defined. Jacobi et al. (2004) clearly depict risk factor typology and the corresponding study designs necessary for identification of risk factors. Most important, a risk must occur *before* the observed outcome. That is, a characteristic can be categorized as a risk factor only if a subject's risk status precedes the outcome of interest. If a characteristic meets all requirements for definition of a risk factor but fails to precede the outcome of interest (e.g., occurs concomitantly with the outcome), then it is considered merely a correlate of the outcome. A correlate is simply a statistical association between the factor and the outcome. A risk factor can therefore be con-

sidered a special type of correlate that occurs before the outcome (Jacobi et al., 2004; Kraemer et al., 1997). An additional typology of risk factors includes a *fixed marker*, which is a risk factor that cannot be changed (e.g., race); a *variable risk factor*, a factor that can be changed or changes spontaneously (e.g., age); a *variable marker*, a variable risk factor where manipulation of the marker does not change the risk of the outcome; and a *causal risk factor*, which is a variable risk factor that changes the risk of the outcome as a result of experimental manipulation (Jacobi et al., 2004).

Determining whether a characteristic is a correlate can be discerned from cross-sectional, epidemiological, case-control, or family history study designs. Because of the precedence requirement, longitudinal studies are the best designs to determine whether a given characteristic meets the requirements for a risk factor. Cross-sectional and longitudinal research designs are both well equipped to discern fixed markers, and longitudinal studies are well suited for discovering variable risk factors. Knowledge gained from these types of studies is limited, however, to inferences about risk factors as causal mechanisms. Although the precedence criterion for risk factors can be met through these studies, it is only through experimental manipulation that causality can be determined. Just because a risk factor consistently precedes an outcome such as a mental disorder, this does not necessarily mean that the risk factor *causes* the disorder. Causality is important for prevention scientists to be maximally effective in preventing the onset or diminishing the effects of mental disorders. A randomized clinical trial, whether preventive or therapeutic in nature, is the only design that will allow researchers to discern whether a variable risk factor is a variable marker or a causal risk factor. Although various research designs provide important information for prevention researchers, from exploratory longitudinal studies to identify definitive risk factors to randomized clinical trials to test the causal status of risk factors that precede the onset of a disorder (Jacobi et al., 2004), it is only the randomized clinical trial design that will allow researchers to make definitive statements about malleability and causality of risk factors.

DISTINGUISHING BETWEEN MEDIATORS AND MODERATORS IN PREVENTION RESEARCH

As Kraemer, Wilson, Fairburn, and Agras (2002) point out, the distinction between mediators and moderators of intervention effects is important for prevention researchers not just conceptually, but also for understanding the importance of each for prevention program evaluation, which in

turn informs developmental theory. Simply stated, treatment moderators determine what treatment works for whom and under what conditions (Baron & Kenny, 1986; Kraemer et al., 2002). Moderators are third variables that affect the direction or strength of the relationship between predictor and outcome variables, and can be qualitative (e.g., gender) or quantitative (e.g., level of reinforcement) in nature (Baron & Kenny, 1986). Ideally, moderating variables are uncorrelated with either the predictor or the outcome variable, but will have an interactive effect with treatment or intervention on the outcome (Baron & Kenny, 1986; Kraemer et al., 2002). Presence of an interaction between moderators and outcomes does not explain the overall effect of treatment, but will help researchers understand individual differences in the effect of treatment. For example, if gender is a moderating variable, it will indicate for whom the intervention will have the most significant effect (e.g., females; Kraemer et al., 2002), but this does not suggest that gender is the causal factor for the observed improved outcomes for females. Even powerful programs will not prevent the targeted disorder for some people; understanding moderators and therefore understanding who is most likely to benefit from the prevention program will help researchers to clarify inclusionary and exclusionary criteria for their program to maximize power in randomized trials (Kraemer et al., 2002).

Although moderators are important for understanding who will be the most responsive to a prevention program, it is treatment mediators that will identify mechanisms of change, or causal links between the prevention program and program outcomes (Kraemer et al., 2002). Identifying mediators will help researchers to understand why program effects occur and identify the mechanism through which the prevention program achieves its positive outcomes, or lack of positive outcomes (Baron & Kenny, 1986; Kraemer et al., 2002). In a prevention trial, determining whether a variable functions as a mediator depends on the extent to which the variable accounts for the relationship between the predictor variables and the outcome of interest (Baron & Kenny, 1986). In other words, a mediator “represents the generative mechanism through which the focal independent variable is able to influence the dependent variable of interest” (Baron & Kenny, 1986, p. 1173); these mechanisms are causal links (Kraemer et al., 2002). Mediators should be strongly related to both the predictor variable and the outcome in a prevention trial so that the intervention condition should predict a change in the mediator, which will in turn be significantly associated with a change in the outcome (Baron & Kenny, 1986; Kraemer et al., 2002).

Tests of mediation in mental health and substance abuse research are severely lacking (Hinshaw, 2002) but are necessary for understanding mechanisms of change in prevention trials and the underlying theory guiding the prevention trial. If a change in a hypothesized mediator is not associated with a change in outcome, or if a change in outcome is observed in the absence of a change in the mediator variable, there may be a problem with the prevention theory (Coie et al., 1993). Furthermore, tests of mediation can allow researchers to elucidate intervention components that are most important to elicit change in the mediating variable, and therefore most important for achieving the desired outcomes (Kraemer et al., 2002).

Prevention scientists need to be cognizant of developmental variables (e.g., age) when examining mediators and moderators of prevention program outcomes. A program to prevent depression, for example, may or may not achieve the same outcomes for middle school students as high school students. If the program achieves similar positive outcomes across the age groups, then developmental variations among participants may not be important to achieving program outcomes. If it is found that age is in fact a moderator, then critical periods in the developmental process of depression can be revealed, including the most effective time to implement a program to prevent depression to achieve the best outcomes (Rutter, 1988).

Identifying mediators and moderators is essential for prevention researchers who want to help the largest number of people with a judicious use of resources. Knowing for whom the treatment works and understanding mechanisms of change in prevention programs will allow prevention scientists to develop the most effective programs for the largest number of people across all levels of risk. Identification of the key ingredients of programs is also possible; programs can then be streamlined so that ineffective program components are modified or eliminated.

RANDOMIZED PREVENTION TRIALS

As noted previously, randomized clinical trials are optimal for determining malleability and causality and whether a prevention program works. The purpose of this section is to discuss why randomized trials are considered the gold standard in prevention research and to describe what could be considered the essential elements of prevention trials that allow prevention research to fully inform developmental theory. The theoretical and methodological guidelines presented here are drawn primarily from Howe, Reiss, and Yuh (2002), who focus on methodological issues associated

with randomized prevention trials, and Coie et al. (1993), who present a conceptual framework for studying the prevention of human disorders.

First and foremost, as stressed previously, is the need for prevention researchers to utilize randomized clinical trial designs. Howe et al. (2002) argue for a hybrid design, called *randomized prevention trials* (RPTs), which combines elements of experimental clinical designs with longitudinal designs. RPTs are uniquely able to test whether the course of psychopathology can be altered through experimental manipulation. The challenge for prevention trials is to provide evidence that the resulting change in the later course of psychopathology is due to the trial itself and not confounding factors. RPTs are better able to do this by utilizing a control or comparison group, with random assignment of participants to intervention or control group conditions. Successful randomization greatly reduces the likelihood that group assignment will be correlated with any other third variable, as well as being better able to control for other possible confounding variables. Results from methodologically sound RPTs will increase confidence in the conclusion that it was the prevention program that led to the changes in outcomes, not a host of other variables that could also be associated with the change in outcome.

The hybrid design espoused by Howe et al. (2002) also includes elements of longitudinal designs, such as repeated measurement of risk and protective factors over the duration of the study. Repeated measurement can test whether change in risk or protective factors is related to change in likelihood of psychopathology. These repeated measures should occur not only with the prevention group, but also with the control group to understand naturally occurring developmental trajectories. Additional information about randomized trials can be found elsewhere (e.g., Friedman, Furberg, & DeMets, 1998; Meinert & Tonascia, 1986). The purpose of this section is not to provide detailed descriptions of randomized trials, but rather to discuss how to set up randomized prevention trials that will bear the most fruit for theoretical implications.

Even in the context of an RPT, prevention programs will have an effect only if the *targeted risk factors associated with the outcome are malleable*. The ability to actually change a risk factor is an essential precondition for using prevention trials to test theory (Howe et al., 2002). Some factors may change naturally, but it is through a prevention trial that the malleability, or *our* ability to change risk or protective factors, can be determined.

The *intervention components must also be linked conceptually to risk or maintaining factors* for certain forms of psychopathology (Hinshaw, 2002). The focus of the pre-

vention trial is to alter risk factors or mediating processes in such a way as to reduce emergence of a disorder; therefore, components that will address those factors or processes need to be included in the intervention design.

An RPT design also allows researchers to test whether a change in risk and protective factors is related to a change in the likelihood of developing psychopathology. Because of the inclusion of a control group and because, by definition, the prevention program is implemented before the emergence of the disorder, it can also be determined whether the change in risk and protective factors preceded the onset of psychopathology, or conversely, whether the emergence of psychopathology shaped the risk and protective factors (Howe et al., 2002). Furthermore, it can lend support for the conclusion that the targeted risk and protective factors were true causal agents and that the change was not due to any other extraneous variables (Howe et al., 2002; Kraemer et al., 1997). Developmental psychopathology theory is supported if the specific risk factors targeted by the intervention have been reduced, and it was the changes in the risk factors that accounted for the improvement in the maladaptive behavior (Baron & Kenny, 1986; Coie et al., 1993).

In a longitudinal design, Howe et al. (2002) argue, RPTs can also serve as *tests of developmental phase and progression*. Expression of psychopathology can show developmental progression over years or decades; expression of psychopathology during different periods in this progression may reflect the effects of different risk and protective mechanisms. RPTs can test this as well as whether the preventive intervention was able to stop progression to later phases by altering risk and protective mechanisms in the current phase. The longitudinal aspects of the design also allow for the detection of possible negative chains of events that may intensify the course of disorder over time.

In addition, well-planned prevention trials can lead to an increased *understanding of causal pathways to dysfunction*. Prevention research is based on theoretical models of how risk conditions are related to adverse outcomes, positing processes that link the risk condition to the negative outcome (Mrazek & Haggerty, 1994; Munoz, Mrazek, & Haggerty, 1996; Reiss & Price, 1996), and theories of prevention should specify developmental processes that alter trajectories toward the onset or maintenance of dysfunction. If the developmental course is changed due to a prevention program and the risk of the disorder or negative outcome is reduced, then the research results will contribute to our understanding of the developmental processes (Cicchetti & Rogosch, 1999; Coie et al., 1993). If the reduction of a targeted risk factor does *not* appear to have changed the pathogenic process, then that risk factor

would not be viewed as a causal agent but may be a marker of atypical development (Cicchetti & Hinshaw, 2002).

Common Design Flaws

Despite adhering to these key theoretical components, Howe et al. (2002) warn against the following common design flaws that limit the informative impact prevention trials can have on theory.

Failure to Measure Important Risk and Protective Factors

Once the arduous task of creating a prevention program is complete, researchers will not realize the full impact of their program unless every factor that is explicitly targeted by an intervention component is measured, especially when multiple component programs are being tested. It is important, however, to consider and measure risk and protective factors that might be influenced by the program, even if they are not direct targets of the intervention. Furthermore, the relevant risk and protective factors need to be tested before and immediately after intervention to demonstrate change as a result of the intervention program, as well as measured more than once across the course of follow-up. This will allow for understanding the role of the targeted risk and protective factors in the etiology of the disorder as well as the mechanisms through which the factors operate (Howe et al., 2002).

Failure to Change Important Risk or Protective Mechanisms

A prevention trial must be able to bring about enough change in the targeted factors to have a long-term effect on later psychopathology. If the targeted risk factors have a low association with the outcome, even though the results may show a reduction in risk, then the program's ability to effect change profoundly will be much lower than if the targeted risk factors were highly associated with the outcome. To combat this problem, researchers can include multiple program components that target a much broader range of risk and protective factors. Alternatively, program components can be added that might not be specifically designed to alter targeted risk factors but are believed to boost the impact and effects of the other program components (Howe et al., 2002).

Breakdown of Randomization

Many researchers will argue that random assignment of participants to conditions is often impractical or simply too

burdensome, and they will employ quasi-experimental designs such as matched controls (Howe et al., 2002). These designs may not be able to eliminate all potential confounds, but with careful attention to the procedures used, they still provide a better avenue than other designs (e.g., simple correlation designs) to test developmental psychopathological theory. Furthermore, randomization does not mean equality of groups, especially because attrition or noncompliance will occur (Howe et al., 2002).

Mediational Confounds

The theoretical impact of RPTs can suffer when mediational confounds (e.g., expectancy effects) are introduced. Although randomization minimizes the impact of potential confounds, a mediational confound can occur when an unintended change in risk or protective factors results from the prevention program. This could happen when, for example, a therapist implements the prevention, and the change occurs due to the therapeutic relationship that develops between therapist and client rather than the prevention program itself. To address this, RPTs can utilize commonly employed procedures in clinical trials such as double-blind placebo controls (Howe et al., 2002).

Moderated Mediation

There will be significant threats to external validity if moderated mediation exists, where a set of targeted risk factors operate differently based on group membership. For example, risk and protective factors may operate differently for boys and girls. When those risk factors are targeted, the prevention program will have different effects on psychopathology for boys and girls. RPTs should test for moderated mediation (Howe et al., 2002).

Lack of Long-Term Follow-Up

As a minimum evaluation requirement, prevention research designs should include long-term follow-up of samples to provide critical information on developmental processes and to track changes in both process and outcome variables into the next developmental stage. RPTs should therefore incorporate an initial assessment of prior history of psychopathology, as well as continued measurement of putative risk and protective factors and psychological functioning (Howe et al., 2002).

Randomized prevention trials that incorporate aspects of randomized clinical trials with longitudinal designs have great potential for improving our understanding of the etiology of disorders and informing the next generation of prevention efforts.

TYPES OF PREVENTION: CURRENT DEFINITIONS OF PREVENTION AND NOMENCLATURE

Thus far we have discussed aspects of prevention science that relate to all prevention efforts, regardless of targeted population or outcome. A solid theoretical foundation for a program tested through an RPT is essential for all prevention work. The term “prevention,” however, is applicable to a wide variety of programs that fall under the umbrella of prevention efforts and often get confused with programs that are actually “treatment.” It seems simple enough to define prevention as “stopping an event from occurring,” but there has been considerable discussion over recent decades of how to define prevention. Because different frameworks have been used to describe prevention, the nomenclature used in the prevention field has changed over time (Durlak, 1997). The original classification system developed in 1957 by the Commission on Chronic Illness was designed as a public health classification system of disease prevention (Mrazek & Haggerty, 1994). The three original types of prevention were primary, secondary, and tertiary (Durlak, 1997; Mrazek & Haggerty, 1994). Primary prevention was an intervention delivered to “normal” populations, or those without disease, to decrease the incidence (new cases) of disorder or illness. The intentions of secondary prevention programs were to decrease the prevalence, or lower the rate, of established cases of disorder or disease. The target populations for secondary programs are those at higher risk for early signs of disease or disorder. Tertiary prevention programs were directed at reducing or eliminating the duration or consequences (e.g., amount of disability) of a disorder (Durlak, 1997; Mrazek & Haggerty, 1994). In this original classification system, however, there was no explicit depiction of the relationship between the mechanisms linking the cause of disease and the outcomes or occurrence of disease. There was little understanding of cause and effect; if an implemented program changed the disease outcome, then it was successful. Early research did not recognize the complex association between risk factors and disease outcomes, including the impact of intervening mechanisms (Mrazek & Haggerty, 1994). Furthermore, because tertiary prevention has been directed at persons with existing disease, it has often been confused with treatment, therapy, or rehabilitation.

With time came a more sophisticated understanding of the complexity involved in the relationship between risk and protective factors and health outcomes, variation in developmental pathways, and empirical ways to test these relationships. A classification system based on these

empirical relationships and a risk-benefit point of view was developed by Gordon in 1987 (Mrazek & Haggerty, 1994). He believed that need and benefits of prevention programs can be examined by comparing an individual's risk of developing a disorder with the cost, risk, or potential side effects of the preventive intervention. Those are usually positively correlated: The higher the risk of developing the disorder, the higher the costs and risk associated with the prevention program. The three categories of prevention Gordon proposed, based on a public health framework, were universal, selective, and indicated preventive programs. His classification stressed the differentiation of prevention from treatment.

The Institute of Medicine (IOM) report (Mrazek & Haggerty, 1994) endorsed a universal, selective, indicated system to differentiate prevention from treatment, drawing primarily on Gordon's (1983, 1987) work. Neither the original (primary, secondary, tertiary) or Gordon's work was designed for mental and substance abuse disorders, so the application to mental health or substance abuse was not straightforward. For example, it is complicated to identify a "case" for mental disorders, and young children may just have cognitive or psychosocial development difficulties rather than an identified mental health disorder (Mrazek & Haggerty, 1994). To address the needs of the mental health and substance abuse fields, the IOM reserves the term prevention to apply to interventions that occur prior to the onset of a disorder (Mrazek & Haggerty, 1994). The IOM endorsed a three-tiered system for prevention:

Universal prevention is applied to everyone in a defined population; participants are not chosen on the basis of any risk factor. Universal programs can often be applied for relatively low cost and risk and typically do not require specially trained professionals to implement. Examples of universal prevention programs include prenatal care and immunization, school-based violence prevention/competency enhancement programs, and behavioral techniques for classroom management (Mrazek & Haggerty, 1994).

Selective prevention is applied to individuals or a subgroup of the population who are at an above-average risk for developing a mental disorder. Examples are home visitation for high-risk infants and preschool programs for children from low-socioeconomic neighborhoods. The risk and cost are justified by the increased risk of illness or disorder, especially if the interventions are moderate in cost with minimal negative side effects (Mrazek & Haggerty, 1994).

Indicated prevention would apply to individuals with early symptoms of mental disorders, or when biological markers indicating predisposition for a disorder but do not meet *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)* criteria. An example of an indicated prevention program is parent-child interaction training for students with behavioral problems. With indicated prevention, the cost may be somewhat high and participation in the program may involve some risk; however, the costs and risk are justified because the needs of the individual are great (Mrazek & Haggerty, 1994).

The two classifications—the original primary, secondary, and tertiary prevention and universal, selective, and indicated prevention—appear to have many similarities, but they have distinct differences. "At times, there even are attempts to use the three-tiered systems interchangeably. This sort of erroneous integration of terms has slipped into the prevention research field and added to the confusion regarding definitions" (Mrazek & Haggerty, 1994, p. 21). Primary and universal prevention are largely comparable, but there are differences that suggest that selective and secondary prevention cannot be used interchangeably. Most important, tertiary prevention or treatment of a disease should not be confused with indicated prevention. Indicated interventions are based on probabilities of a disorder developing rather than the treatment of an existing condition (Mrazek & Haggerty, 1994).

The IOM report (Mrazek & Haggerty, 1994) posits prevention as just one part of the whole spectrum of interventions for mental disorders. Treatment would be applied to individuals who are in immediate need for therapeutic interventions (e.g., psychotherapy) for *DSM-IV* disorders (or those who closely meet *DSM-IV* criteria). Maintenance programs are for those with *DSM-IV* disorders who require ongoing care (Mrazek & Haggerty, 1994).

The general prevention strategies are often integrated within an overall public health plan. For example, a universal intervention can be applied to a population where the benefits for the general public far outweigh the risk. Selective programs can be implemented to target those individuals with significant risk factors that warrant the use of a higher-cost, higher-risk program. Indicated programs can be designed for those individuals showing early signs of a disorder, with the intent to prevent more serious dysfunction and the onset of the full-blown disorder (Mrazek & Haggerty, 1994). Despite our best efforts, there will still be individuals for whom the prevention programs were not effective, and those persons will need access to treatment programs to address their needs.

Building on the definitions and nomenclature offered in the IOM report on prevention, Kellam and colleagues (Ialongo, Kellam, & Poduska, 2000; Kellam & Rebok, 1992) offer a schema for organizing preventive intervention efforts in K–12 school settings that involves multiple levels of interventions nested in a public health/human services system. At the first level, *universal interventions* (Mrazek & Haggerty, 1994) are applied to the population as a whole. At the second level, *selective interventions* are targeted at children at risk for disorder based on some known risk factor such as parental divorce. *Indicated interventions* are at the third level and back up the first and second levels. At the fourth and final level are treatment services for those individuals who fail to benefit from the universal, selective, and indicated interventions. The first, or universal, level addresses the socialization structure and processes by which public institutions such as schools foster social, cognitive, emotional, and behavioral development. The second and third levels are typically more specialized and may feature a more remedial focus rather than strengthening the socialization structures in institutions such as Head Start, grade school, and/or the family. The fourth level, treatment services, typically involves the provision of highly specialized habilitative or rehabilitative care within traditional mental health or substance abuse treatment settings.

Kellam and colleagues (Ialongo et al., 2000; Kellam & Rebok, 1992) make the case that the costs and benefits of selective and indicated preventive interventions and treatment services are likely to be optimized if nested in a universal intervention. First, an individual's response to a universal intervention, as opposed to crudely measured risk factors at a single point in development, could be used to more accurately determine the need for more intensive intervention in the form of indicated or treatment interventions. Second, if the universal intervention proves effective, then the number of individuals in need of an indicated or treatment intervention is reduced. For those who require additional interventions beyond the universal intervention, the impact of the selective, indicated, and treatment interventions may be enhanced if the key figures in the social contexts the individual operates within are partners in the intervention. For instance, in the case of a child receiving a treatment intervention for conduct problems based on social learning principles, the clinician is quite likely to involve the teacher in any behavior change program. If the teacher has some background in social learning theory and its therapeutic applications, the task of involving the teacher should be much easier for the clinician.

The Johns Hopkins University Preventive Intervention Research Center's (JHU PIRC) ongoing intervention development efforts in the Baltimore City Public Schools embody this nested approach to preventive and mental health and substance abuse services. The JHU PIRC has developed and is now evaluating a universal parenting and classroom behavior management preventive intervention. In addition, the JHU PIRC is developing a system for assessment and identification of mental health and substance abuse service needs and linkage to mental health and substance abuse services for the participating children and families. This system of identification and linkages builds on the integration of a school-based mental health specialist into a school-level interdisciplinary team. This team is responsible for seeing that the mental health needs of the children are met along with their social and physical health needs. Through the school-based mental health specialist and the school-based interdisciplinary team, the JHU PIRC is developing a network of linkages to mental health and substance abuse treatment providers in Baltimore. The JHU PIRC also is developing a set of first-stage, or screening, assessment tools that will be used by teachers and parents to identify children and families who may be in need of mental health and/or substance abuse services. Those children and families identified to be in need based on these first-stage measures are then referred to the school-based mental health specialist and interdisciplinary team for a more comprehensive assessment and the development of a treatment plan. In the event the plan calls for linkage to mental health and substance abuse treatment service providers in the community, the mental health specialist serves as the family's advocate and liaison to those agencies and remains in a case manager role throughout the process.

In addition to assessment and linkage to services, the role of the mental health specialist includes (1) training and supervising teachers in identification of children and families in need of mental health services; (2) consulting with and training teachers on the use of effective classroom behavior management strategies; (3) training and supervising the paraprofessionals who lead the universal parenting intervention; (4) providing on-site, time-limited mental health services to families and children; (5) developing and maintaining a computer databank of available mental health and substance abuse services in the community; and (6) establishing contractual agreements with the local mental and substance abuse treatments providers for on-site services whose costs are covered through third-party billing.

THE PREVENTION INTERVENTION RESEARCH CYCLE

The implementation of prevention programs, is not something that can be done quickly or haphazardly. A series of carefully planned sequential steps are required to achieve maximum benefit for program outcomes as well as future prevention efforts (Mrazek & Haggerty, 1994).

Step 1 in the research cycle is to identify the problem or disorder that is to be the target of the intervention and to gather appropriate knowledge of the disorder (e.g., incidence and prevalence) to first determine whether a preventive intervention is warranted. Information important to consider when deciding whether the intervention is warranted is the potential personal, economic, and social cost of the disorder to communities. It is at this point in the cycle when partnerships between researchers and community members should be forged. Partnering early with community members is essential to make sure the problem or disorder is actually an important issue for the community and to determine community responsiveness and the feasibility of implementing programs in that community (Mrazek & Haggerty, 1994).

Once a specific disorder or problem is identified as the target for a preventive intervention, *Step 2* in the cycle is to review risk and protective factors from the knowledge base gathered in Step 1. Knowing the critical risk factors associated with onset of the disorder is critical for decisions about the nature of and targets for a prevention strategy. A variety of research disciplines can be examined for this information, including molecular biology, behavioral and molecular genetics, gene-environment interactions, developmental, experimental, and social psychology, behavior analysis, developmental psychopathology, and epidemiology, among others (Mrazek & Haggerty, 1994).

Step 3 begins the process of designing, conducting, and analyzing the research program. Once the pertinent information is collected, the researcher is ready to begin an exploratory or pilot study and confirmatory and replication studies to determine the efficacy of the program (i.e., that the program produces a beneficial result under ideal conditions). It is during this stage that many decisions are made about the prevention program, such as intervention techniques, implementation sites, and participant recruitment. It is important at this stage to integrate knowledge from Steps 1 and 2 and design the prevention program based on your chosen theoretical model. The choice of a theoretical model comes not only from information about risk and protective factors, but also from analysis of inter-

vention research. According to the IOM report (Mrazek & Haggerty, 1994), the most current evidence supports the risk-reduction model as a strong theoretical basis for preventive interventions. That is, the most productive strategy for researchers when choosing a theory and designing the resulting prevention programs is to focus on the reduction of risk and/or the enhancement of protective factors.

Step 4, conducting large scale field trials, offers an opportunity to expand Stage 3 work for programs that were found to be efficacious. Replicating the program in large-scale trials in the community allows for a more realistic assessment of benefits and costs of the program as well as generalizability of the program in naturalistic settings with regard to different personnel, participants, settings, cultures, and conditions. Although researchers may theoretically be in charge, they will quickly lose control of the program unless a great deal of attention is given to the implementation and data collection procedures. If community members have been involved with program development from the beginning, this stage may flow more smoothly. Regardless of how well designed a program is, a single randomized field trial is not enough evidence to support large-scale community implementation of the program. Multiple generations of trials and multiple sites may be necessary before the core elements of a prevention program can truly be determined. After multiple field trials have determined the key ingredients of an efficacious program, a final field trial will be necessary to determine the program's effectiveness (e.g., Does the program do what it is intended to do?). For this trial, although the research protocol stays in place, much of the implementation of the program is handed over to the organization that hopes to run the program (Mrazek & Haggerty, 1994).

The last stage of the cycle, *Step 5*, is facilitation of large-scale community implementation and ongoing evaluation of the program. For this stage, the researcher should provide a manual to community members to guide program implementation. At this point, after repeated field trials in Stage 4, it will also be known which components of the program are core ingredients and which components may be modified to suit the needs of the community. Providing a manual to the community implementers will help them in making decisions about if and how to modify the program. Also, the researcher can continue to be involved with the community by facilitating decisions regarding ongoing community-based evaluation of the program, though control over implementation at this stage is the primary responsibility of the community organization.

ISSUES IN THE USE OF INDICES OF RISK FOR IDENTIFYING AND SELECTING INDIVIDUALS FOR PREVENTIVE AND TREATMENT INTERVENTIONS

Step 2 in the prevention intervention research cycle requires the careful identification and selection of individuals for the prevention program, and this becomes especially important when implementing a multiple-tiered prevention model to clearly define the criteria for qualification for more intensive intervention if necessary. However, as Kraemer et al. (1999) point out, the identification and selection process involves a series of difficult choices that cannot be based on statistical significance alone. Kraemer et al. provide a comprehensive compilation of measures of association that have been employed in research on risk and protective factors. They point out that no one measure of association is superior to the others when it comes to identifying individuals at risk for untoward outcome and in need of intervention. Implicit in Kraemer et al.'s thesis is that perfect prediction or diagnostic accuracy is the exception rather than the rule in the domains of health and behavior.

Kraemer et al. (1999) go on to argue that when engaging in social policy or clinical decision making based on the assessment of risk and protective factors, decision makers need to consider a number of issues: (1) the cost of the intervention and the screening and identification process, (2) any iatrogenic effects associated with the intervention to be employed and the screening and identification process, (3) the population base rate of the targeted disorder, and (4) the effectiveness of the intervention in reducing the population base rate of the targeted disorder. Kraemer et al. offer three decision-making scenarios that may arise. The first is where the intervention and screening and identification processes are relatively cheap and there are minimal or no iatrogenic effects associated with either. However, the population base rate of the disorder is either modest and/or the intervention only moderately effective in reducing the population base rate. In such a case, decision makers may want to choose a cutoff on their index of risk that minimizes false negatives (i.e., incorrectly concluding that an individual will not develop the targeted disorder), while largely ignoring the rate of false positives (i.e., incorrectly concluding that an individual will develop the targeted disorder). In this scenario, by employing a cutoff that minimizes false negatives and ignores false positives, one is likely to achieve a greater reduction in the population base rate of the disorder given that a large proportion of the population at risk for the disorder will be ex-

posed to the intervention. The fact that the intervention is inexpensive and without major iatrogenic effects should serve to assuage concerns about the potential for a high rate of false positives.

A second scenario that Kraemer et al. (1999) offer for consideration is when the intervention may be costly and/or feature the potential for serious iatrogenic or side effects. Moreover, the population base rate of the targeted disorder and the effectiveness of the intervention are relatively high. In such a case, one might want to choose a cutoff on the index of risk that minimizes false positives while largely ignoring false negatives. Given that both the population base rate and intervention effectiveness are high, one can afford a high false-negative rate and still potentially make a substantial reduction in the population base rate of the identified disorder.

Kraemer et al. (1999) offer a third scenario that appears much more realistic when it comes to preventing mental disorders. In this scenario, the intervention and assessment and identification process is likely to be expensive, but both the population base rate and the effectiveness of the intervention will be modest. Consequently, the decision maker will want to place equal emphasis on reducing both false negatives and false positives. Petras, Kellam, Brown, Poduska, and Ialongo (2003) provide an empirical example of the use of Kraemer and colleagues' framework in the context of a study of the diagnostic utility of teacher ratings in identifying elementary school children at risk for committing a violent act in adolescence. Petras et al. employ a software program developed by Kraemer to carry out analyses that allow one to compare and contrast variations on the scenarios described earlier in predicting outcomes of interest. Ultimately, as Kraemer et al. point out, the choice of a cut point will not be based on statistics, but on what the social policy and clinical decision makers judge to be acceptable in terms of the consequences of emphasizing one form of misclassification versus the other, or attempting to achieve a balance between the two.

A DEVELOPMENTAL EPIDEMIOLOGIC FRAMEWORK FOR PREVENTION

Although this chapter argues for a developmental psychopathology approach to prevention, it does not imply that other theories or approaches are not important to prevention work, or that a developmental psychopathology approach cannot be incorporated into other approaches to prevention. For example, Kellam and Rebok (1992) and Ia-

longo et al. (2000) propose a developmental epidemiologic framework for preventive intervention research that draws on concepts and principles from developmental psychopathology as well as life course development, community epidemiology, and public health perspectives. The interdisciplinary perspective reflected in Kellam and colleagues' (Kellam & Rebok, 1992) *life course/social fields* framework for prevention is consistent with recent advances in mental health and substance abuse research that have caused investigators to question to whom their research findings pertain and the role of context in shaping human development. Indeed, current sampling procedures often leave uncertain the populations of individuals or families to whom the research findings can be generalized. That is, the sample is not representative of a defined population. Serving to highlight the need for defining the population under study is the fact that the frequency and distribution of the causal processes that put children and their families at increased risk may vary across social contexts such as neighborhoods or communities. In Kellam and colleagues' view of prevention and mental health and substance abuse services research, the need for defining the population under study is particularly important because the causal model provides the specific targets for our preventive and mental health and substance abuse services interventions. For example, a preventive intervention aimed at reducing the risk of antisocial behavior is likely to be of little value to a community if the prevalence of the targeted risk factors (e.g., exposure to deviant peers) or processes (e.g., inept parenting practices) in that community is quite low. An alternative causal model and preventive intervention may be a better fit for that community. Finally, Kellam and colleagues' adoption of an interdisciplinary perspective stems from the fact that the causal models of psychopathological development are frequently limited by the absence of attention to relevant aspects of the environmental context.

Life Course Development

As indicated earlier, the developmental epidemiologic framework offered by Kellam and colleagues reflects a life course development orientation. Life course development focuses on the mapping of developmental paths, including antecedents, mediators, and moderators of developmental processes and consequences (Kellam, Branch, Agrawal, & Ensminger, 1975; Kellam & Ensminger, 1980; Kellam & Rebok, 1992). Research on developmental paths that includes searching for antecedents and elements that enhance or inhibit developmentally appropriate outcomes is viewed in the context of variation in

individuals within defined populations. The purpose of carrying out research on developmental paths is to uncover aspects of developmental models that may be important in the developmental and etiological outcomes *and that are amenable to intervention trials*.

Central to Kellam and colleagues' (Kellam & Rebok, 1992) life course/social fields framework is the concept that individuals face specific social task demands in various social fields across the major *periods* of the life span (Kellam & Rebok, 1992). The social task demands that the individual confronts are defined by individuals in each social field, referred to as *natural raters*. The natural rater not only defines the tasks but also rates the individual's performance in that social field. Parents function as natural raters in the family, peers in the peer group, and teachers in the classroom (Kellam, 1990; Kellam et al., 1975; Kellam & Ensminger, 1980). This interactive process of demand and response is termed *social adaptation*, and the judgments of the individual's performance by the natural raters is referred to as *social adaptational status* (SAS; Kellam et al., 1975).

In contrast to SAS, *psychological well-being* (PWB) in Kellam and colleagues' (Kellam & Rebok, 1992) framework refers to the individual's internal state, as reflected in anxious and depressive symptoms and mood disorders. They hypothesize that PWB and SAS are intimately related, such that PWB is in large part determined by the degree to which the individual is successful in meeting the demands of his or her natural raters. Kellam and colleagues' conceptualization of the link between SAS and PWB is grounded in the basic principles of social learning theories of depression (Bandura, 1978). The more successful individuals are in meeting the demands of their natural raters, the more likely they will be reinforced for their successes. Alternatively, failure to meet the demands of the natural raters will be associated with reductions in reinforcement and increased punishment, which may then lead to decrements in PWB. In terms of the influence of PWB on SAS, the concentration problems that often accompany depressed mood may serve to disrupt the mastering of new, or complex, social task demands (Kovacs & Goldston, 1991), leading to social adaptational failure. Moreover, the feelings of hopelessness, helplessness, and low self-efficacy frequently associated with depressed mood may also reduce the likelihood that the individual will succeed in meeting social task demands that require sustained concentration and effort (Kovacs & Goldston, 1991).

In line with the organizational approach to development (Cicchetti & Schneider-Rosen, 1984), Kellam and colleagues (Kellam & Rebok, 1992) view normal development

as marked by the integration of earlier competencies into later modes of function, with the earlier competencies remaining accessible, ready to be activated and utilized during times of stress, crisis, novelty, and creativity. It follows, then, that early successful SAS in the face of prominent developmental challenges tends to promote later adaptation as the individual traverses the life course and encounters new and different social task demands across the main social fields (Cicchetti & Schneider-Rosen, 1984). This key developmental principle, along with a growing empirical literature, forms the basis for Kellam and colleagues' focus on early adaptation to social task demands as a means of improving SAS and PWB over the life course and preventing mental disorders and substance use (Ialongo et al., 2000; Kellam & Rebok, 1992).

Community Epidemiology

The community epidemiologic perspective also is represented in Kellam and colleagues' (Kellam & Rebok, 1992) developmental epidemiologic framework for prevention. Community epidemiology is concerned with the nonrandom distribution of a health problem or related factor in a fairly small population in the context of its environment, such as a neighborhood, school, or classroom. Community epidemiology provides a means of identifying variation in developmental paths, including the roles of antecedents, mediators, and moderators, as they vary in frequency and function within and across different subgroups and contexts of a defined population. Traditionally, the phrase "host/agent/environment" is part of the epidemiological lexicon (Morris, 1975). It refers to a way of conceptualizing cause or etiology as involving vulnerability in the person (the host), conditions in the environment as producing illness, and a causal process of interaction (the agent) between the individual and environmental risk conditions. Thus, the integration of life course development with community epidemiology allows the study of variation in developmental antecedents and paths in a defined population in defined ecological contexts.

Defining the Ecological Context

From a community epidemiologic perspective, a neighborhood can be defined in terms of its geographic boundaries and its sociodemographic characteristics—particularly those social indicators that may be relevant to mental health and substance abuse research. The Health Demographic Profile (Goldsmith et al., 1984) developed by the National Institute of Mental Health's biometry and epi-

demiology branch, using census data, provides a means of rapidly characterizing neighborhoods with respect to small area social indicators that have been found to be related to the incidence and prevalence of mental disorder. In fact, the original Health Demographic Profile was developed to determine the need for community mental health centers in neighborhoods and communities across the country based on small area social indicators. That is, the small area social indicators were used to predict the rate of mental disorder in the community and to estimate the need for mental health services based on that rate.

The Advantages of Defining the Ecological Context

With the use of samples of convenience or clinic samples, participants tend to be viewed in isolation from their socioenvironmental characteristics. For example, the characteristics of a child's classroom, peer group, family, or neighborhood cannot be included as precisely as needed to understand variation in intervention impact or variation in the developmental course. The community epidemiologic perspective is in keeping with Bronfenbrenner's (1979) admonition to consider the determinants of human development arising from the broader environment in which children and families are embedded.

Effects of the Classroom Social Ecology

In terms of evidence that supports the need for a community epidemiologic perspective in designing and evaluating preventive intervention trials, Kellam, Mayer, Rebok, and Hawkins (1998) found that the level and duration of response to school-based preventive interventions may vary as a function of the characteristics of the child's classmates and of the classroom and school. More specifically, they found that the risk of being rated highly aggressive in middle school for boys varied as a function of the level of aggression in the first-grade classroom, after controlling for the youth's level of aggression in first grade. That is, controlling for boys' level of aggression in first grade, boys in first-grade classrooms rated highly aggressive were at 4 times greater risk of being rated as aggressive in sixth grade than boys who were in low-aggressive first-grade classrooms.

As another example of the potential impact of classroom/school characteristics on intervention outcomes, large class sizes may serve to reduce teachers' capacity to adequately and consistently monitor and discipline each of their students. Moreover, either of the above—high rates of disruptive behavior and/or large class sizes—may result in teachers spending less time on rehabilitative work with

students who are falling behind academically and/or who are aggressive.

Effects of the Neighborhood Social Ecology

A community epidemiologic perspective leads prevention scientists to study factors operating at the level of the neighborhood that may influence the risk for a mental disorder or the effects of preventive or services interventions (Brook, Nomura, & Cohen, 1989). In the case of the former, the risk of depression for African American adults in the NIMH Epidemiologic Catchment Area studies varied as a function of the racial composition of the neighborhood they lived in (Goldsmith et al., 1984). If one were African American and lived in a majority African American neighborhood, one was at lower risk for depression than if one were in a majority White neighborhood. Without careful definition of the population and its social context, such phenomena may not have been discovered.

As to neighborhood influences on the effects of preventive interventions, consider an intervention aimed at preventing substance use. Whether such an intervention is successful may vary with the availability of substances in the neighborhood: The greater the availability, the greater likelihood of use. Consequently, one may see poorer intervention response in neighborhoods with high availability (Johnston, O'Malley, & Bachman, 1995; Office of Applied Studies, Substance Abuse and Mental Health Services Administration, 1995). In addition, the individual youth's attitudes and beliefs about substance use may be shaped by the prevailing attitudes and beliefs at the level of the neighborhood. In a neighborhood where the prevailing attitudes are accepting of substance use, the individual's attitudes may become more accepting as well. Johnston et al. found that as disapproval and perceptions of harm of marijuana use have decreased since 1992, use of marijuana has increased. Relatedly, Crum, Lillie-Blanton, and Anthony (1996) report that Baltimore youths living in neighborhoods in the highest tertile of crime and drug use were 3.8 times more likely to have been offered cocaine than youths in the lowest tertile.

In terms of neighborhood influences on preventive interventions aimed at educational outcomes, children in neighborhoods characterized by high levels of unemployment may perceive that regardless of their academic efforts and successes, high-paying jobs may be unattainable once they enter the workforce. Consequently, they may be less likely to demonstrate sustained academic effort and more likely to drop out of school. An additional factor operating at the level of the neighborhood that may influence intervention

response is the availability of formal support systems, such as affordable, quality child care services and well-supervised afterschool programs that provide children with opportunities to engage in appropriate educational, recreational, and social activities. Finally, the availability of child and family mental health and substance abuse services may serve to influence intervention response through direct facilitation of adaptation to normative developmental demands and/or by facilitating children's coping with failure to meet task demands, either through psychosocial or pharmacologic means.

The Community Epidemiologic Approach versus the Use of Weighted National Samples

Community epidemiology (as distinguished from the use of weighted national samples) is well suited for analytic and explanatory goals of preventive and mental health and substances abuse services research. More specifically, utilizing community epidemiologic principles and methods, one can hold constant the macro characteristics of a population, for example, an urban neighborhood. One can then examine diverging developmental paths in the context of variation in small social fields such as family, classroom, and classmate/peer group within that neighborhood. In contrast to the community epidemiologic approach, the use of weighted national probability samples leaves one with too few cases in any one ecological context to study the effects of that context on development.

Community Epidemiology and Sampling

The community epidemiologic perspective offers a number of advantages, particularly with respect to sampling. Volunteer samples, or samples drawn from clinics, come from unknown total populations. Such samples typically entail selection bias because those families who volunteer or who seek help may be different in important aspects from families with similar problems who do not (Greenley & Mechanic, 1976; Greenley, Mechanic, & Cleary, 1987; Kellam, Branch, Brown, & Russell, 1981). Those who seek help from the church may be quite different from those who seek help from the clinic. Subjects in volunteer or clinic samples differ from the general population by the very fact that they seek help (Kellam et al., 1981). Relying on volunteer participants in prevention or services intervention trials sought through newspaper or poster advertising has similar problems. Those who respond may not be representative of those who do not. Of note, the work of Leaf, Alegria, and Cohen (1996) and others (Oxford, Boyle, & Szatmari, 1987; Zaner, Pawelkiewicz, De-

Francesco, & Adnopo, 1992) suggest that fewer than 25% of children and adolescents in need of mental health services receive such services. Thus, the children who do come to mental health specialty clinics represent only a fraction of the population with mental health problems.

Among the most critical of the potential biases associated with the use of clinic samples is the tendency for only the most socially impaired children to be referred to and seen in clinics (Berkson, 1946; Caron & Rutter, 1991). Indeed, Caron and Rutter demonstrate that the prevalence of psychiatric disorders and their comorbidity are vastly overestimated when clinic-based samples are used. In avoiding this bias, epidemiologically defined community samples ensure that generalizations to known populations can be drawn and the degree of social and cognitive impairment associated with psychiatric symptoms, syndromes, or disorders, along with their incidence, prevalence rates, and comorbidity, can be validly inferred (Kellam, 1990). In the absence of such data, informed decisions with regard to the allocation of the limited treatment and preventive intervention services available are difficult to make (Kellam, 1990; National Institute of Mental Health, 1991). Thus, mental health service needs may go unmet.

An Understanding of Who Participates and Who Does Not

An additional advantage of the community epidemiologic perspective is that few samples are likely to be complete in the sense of all members of the targeted population being constantly and continuously available. Prevention or treatment research with children is particularly difficult given the mobility of families. Here, a community epidemiological orientation providing information about the total population offers an understanding of who participates compared to those who do not.

Community Epidemiology and the Efficiency of Multistage Sampling

Research on developmental antecedents, paths, and outcomes from a *life course* perspective requires population-based measurement designs that control for selection bias in ways that samples derived from clinics or voluntary samples cannot. In turn, developmental epidemiologically based research requires ecologically valid and economical measures, which provide important information about the characteristics of the individuals in the population and the antecedents, mediators, and moderators of developmental processes and consequences. These measures should also inform us of the extent to which developmental outcomes and their putative mediators and moderators vary in fre-

quency and function within and across different subgroups of a defined population in the context of a community.

An important strategy for maximizing efficiency in epidemiologic research is the multistage sampling strategy (Anthony, 1990). It conserves resources by using efficient assessments of large population-based, probabilistic samples and more expensive and burdensome assessments on subsamples selected by reason of supposed high risk (Anthony, 1990). Through multistage, representative sampling, the data from our first-stage, or population-based, measures can be used to draw smaller samples for studies requiring more frequent and comprehensive measurement and close laboratory control. Population estimates for the more intensive measures can be made through use of sample selection weights (Anthony, 1990).

First-stage, or population-based, measures can serve at least three key functions in preventive intervention field trials. First, they can be relied on to provide measures of intervention effects and outcomes. Consequently, they need to be reliable and sensitive measures of change that can be briefly and economically administered to the entire population of interest. Second, they can be used to identify individuals from the population in need of selected or indicated preventive interventions or treatment. As noted earlier, Kellam and Rebok (1992) and Ialongo et al. (2000) advocate a nested approach to preventive and mental health and substance abuse services interventions, with universal preventive interventions serving as routing mechanisms to selective and/or indicated interventions. That is, first-stage measures are used to measure response to the universal interventions and, as such, serve to identify individuals in need of more intensive mental health and substance abuse services.

Thirdly, first-stage measures can provide the needed bridge for linking developmental epidemiology to studies based on more frequent or precise observations on smaller samples. That is, research on total cohorts within specified populations can be related through multistage representative sampling to microanalytic studies on selected smaller populations requiring more frequent measurement and close laboratory control. For example, a smaller, stratified probability sample was drawn from the first cohort of elementary school children who participated in the JHU PIRC trials (Mirsky et al., 1991). This subsample was drawn to study attention/concentration processes in young children. The sample was selected using relevant first-stage measures that were administered to the entire cohort briefly and economically. This second-stage sample was drawn to represent the stratum from which it was derived as well as the total population. The first-stage

measures revealed an intimate relation between teacher-rated concentration problems and aggressive as well as shy behaviors, classroom achievement, and depression. The representative smaller sample studied periodically with more precise measures of attention confirmed the associations and specified the kinds of attention deficits involved (Mirsky et al., 1991). These results then led to the inclusion of attention deficits in our analyses of impact of the JHU PIRC's preventive trials and to the development of new trials for children at risk for attention disorders.

As Kellam (1990) has noted, this same approach could be used to identify cases of interest for research on etiology. For instance, Ialongo, Reider, and Kellam (2005) were interested in studying the prognostic power of young children's self-reports of depressive and anxious symptoms. Detailed psychiatric assessments were carried out in the context of a multistage sampling design. At the first stage, a relatively economical yet sensitive screening instrument was used to identify cases for more precise and comprehensive assessment at a second stage. A random stratified sampling procedure was then employed at the second stage to select representative samples of children from the entire distribution of scores on the first-stage measure of depressive symptoms. Bird, Gould, Yager, Staghezza, and Canino (1989) and others (e.g., Offord, Boyle, & Racine, 1989) provide examples of the use of multistage designs to estimate the prevalence of psychiatric disorders in children and adolescents. Bird et al. and Offord et al. used the Child Behavior Checklist (CBCL; Achenbach, 1991) at the first-stage or population level, which is likely one of the most well researched and psychometrically sound first-stage or screening measures of child and adolescent psychopathology. The administration of the CBCL was followed by clinical interviews at the second stage for those children identified as cases by the CBCL and a random-stratified sample of controls (Bird et al., 1989; Offord et al., 1989).

Anthony (1990) describes how a multistage sampling strategy can be incorporated into a longitudinal, prospective design. At each longitudinal assessment, new cases are identified through the use of the first-stage measure(s) administered at the population level. For each new case, matched controls are drawn from the remaining noncase population for more intensive study, along with the previously identified cases and their second-stage controls. This link between population-based epidemiological research and the smaller samples required for microanalytic study shows great promise for future prevention research.

Each of these designs are variants of the case-control design, which provides an efficient means of studying rela-

tively rare disorders or phenomena (Lilienfeld & Stolley, 1994; Schlesselman, 1982). In the case-control design, a suitable number of matched controls are drawn for each case. The controls may be drawn from the same classroom or school or neighborhood, depending on the investigator's hypotheses with respect to the level of the ecological context that will contribute the most to understanding the phenomena of interest. Snow's (1849) work on the outbreak of cholera in nineteenth-century London aptly illustrates the advantage of a case-control design. While comparing cases of cholera to cholera-free, matched controls, Snow discovered that the discriminating factor was the use of a particular public well. The cases used it, and the controls did not. Subsequently, this public well was established as the source of the cholera.

In summary, these uses represent some of the most important reasons Kellam and colleagues (Ialongo et al., 2000; Kellam & Rebok, 1992) argue for drawing on community epidemiologic principles and concepts in designing and evaluating preventive intervention field trials. Community epidemiology provides the methodology for obtaining population rates and distributions of antecedents and outcomes, and tools and concepts for integrating disciplines into a broader, more ecological perspective for preventive intervention research.

The Public Health Perspective

In addition to life course development and community epidemiology, the developmental epidemiologic framework that Kellam and colleagues (Ialongo et al., 2000; Kellam & Rebok, 1992) offer for preventive intervention research features a public health perspective. An important advantage of the public health perspective is that the diffusion of effective programs is facilitated by partnerships fostered with the major institutions charged with the public's health, education, and welfare. Preventive intervention efforts are developed in conjunction with personnel from the institutions expected to implement them and are integrated into the ongoing activities of those institutions. This serves to better ensure that once the research funds are no longer available, the institution retains a trained cadre of interveners with the materials and protocols necessary to sustain effective programs. In line with the public health perspective, one way prevention scientists can ensure the dissemination and acceptability of interventions is to enter into a partnership with the existing public institutions mandated by the city, county, or state to meet the needs of the populations they serve. By way of example, Kellam and colleagues describe a partnership with the Baltimore City

Public School System (BCPSS), which was the basis for two generations of preventive intervention trials that are described in more detail later in the chapter. Kellam and colleagues' partnership with the BCPSS evolved to the point that members of their research team were integrated into the BCPSS's curriculum, parent involvement, special education, and mental health and substance abuse services planning committees. Consequently, the preventive interventions represented not only what the BCPSS thought was affordable and feasible, but also the directions in which the BCPSS was going in terms of new initiatives in the areas of curriculum, parent involvement efforts, and mental health and substance abuse services. Each element of the interventions reflected the thinking of the BCPSS superintendent, administrators, principals, and teachers. In addition, each element of the interventions was piloted with feedback solicited not only from principals, teachers, and school social workers/psychologists, but also from parents and children. Moreover, rather than importing experts to provide preventive services, existing school staff—principals, teachers, school psychologists and social workers—collaborated on the development, implementation, and evaluation of the preventive intervention trials. Thus, this public health approach allows Kellam and colleagues to confirm the applicability of findings from laboratory and microanalytic studies to population settings and to ensure that the public benefits of large-scale interventions outweigh public costs (Kellam, Rebok, Ialongo, & Mayer, 1994; Kellam, Rebok, Mayer, Ialongo, & Kalodner, 1994). Strong collaborative partnerships are also necessary for population-based intervention trials requiring random assignment of teachers, children, and families to intervention and control conditions.

Pentz (1993) and others (Perry et al., 1996; Wagenaar, Murray, Wolfson, Forster, & Finnegan, 1994) offer examples of large-scale community preventive intervention efforts involving strong collaborative partnerships with local, county, and statewide institutions. Minkler (1990) provides a theoretical model for developing collaborative relationships with the institutions integral to the public's mental health, along with the pragmatics of achieving a successful collaboration. Jason (1982) has described similar partnership strategies for developing community and institutional support. Such partnerships require considerable time to build, along with a mutual sense of trust and shared interests (Kellam et al., 1975). Kellam and colleagues' initial intervention efforts in the Baltimore public schools required a 30-month development period. Such prolonged start-up times may serve to deter most prevention researchers. But once such collaborations are developed, they

prove productive to the institutions involved, reducing start-up times for future research efforts.

ILLUSTRATIVE EXAMPLES OF UNIVERSAL PREVENTIVE INTERVENTIONS: THE JOHNS HOPKINS PREVENTIVE INTERVENTION RESEARCH CENTER (JHU PIRC) FIRST AND SECOND GENERATION TRIALS

In this next section, we provide illustrative examples of developmentally oriented universal intervention trials. Besides providing an overview of the underlying conceptual framework for the interventions and the design of the trials, findings are presented that illustrate the use of prevention intervention trials to test developmental theory.

Overview of the Rationale and Design of the Johns Hopkins Preventive Intervention Research Center Trials: The First-Generation Trial

In response to the relative dearth of well-controlled, longitudinal evaluations of preventive interventions targeting the early antecedents of substance abuse, depression, and anti-social behavior, the JHU PIRC mounted two first-grade, universal, preventive intervention trials in collaboration with the Baltimore City Department of Education. In the initial, or first-generation, JHU PIRC intervention trial, two theory-based preventive interventions were evaluated in two consecutive cohorts of approximately 1,000 first-graders in the 1985 to 1986 and 1986 to 1987 school years in 19 Baltimore city schools. One intervention, the Good Behavior Game (GBG; Barrish, Saunders, & Wolfe, 1969), was aimed at aggressive disruptive behavior, whereas the other intervention, Mastery Learning (ML; Guskey, 1985), targeted poor academic performance. The two universal classroom-based interventions were implemented over first and second grades for each of two cohorts.

Five different urban areas within one large elementary school district in eastern Baltimore were selected with the involvement of the Baltimore City Planning Department. Each of these five urban areas varied in terms of socioeconomic and ethnic characteristics. In each urban area, three or four schools were selected that were well matched with regard to census tract, school level, and first- and second-grade data. Within these clusters of schools, by a random process, one school received the ML intervention, one the GBG intervention, and one served as a control school (to provide protection against within-school contamination). In each intervention school, children were randomly as-

signed to classrooms. Classrooms not receiving any interventions were included as internal controls, thus holding constant school, family, and/or community differences such as the effect of the principal on school environment. Teachers also were randomly assigned to intervention conditions. Both interventions were applied at the classroom level by the teacher after intensive training. Baseline assessments were carried out before initiation of the intervention. Intervention and control teachers received equal attention and incentives. The training sessions continued throughout the intervention period (grades 1 and 2 for both cohorts) for approximately 40 hours for each intervention. Control teachers were involved in meetings, workshops, and seminars not related to intervention targets.

The GBG, which was directed at improving classroom aggressive behavior, involved the systematic use of behavior modification for classroom management. The GBG was selected because of its earlier demonstrated efficacy and acceptability to the schools and the community. ML is a teaching strategy with demonstrated effectiveness in improving achievement. The theory and research on which ML is based specifies that under appropriate instructional conditions, virtually all students will learn most of what they are taught (Block & Burns, 1976; Bloom, 1976, 1982; Dolan, 1986; Guskey, 1985).

The immediate results of this initial JHU PIRC trial yielded evidence that the proximal targets of poor academic performance and aggressive disruptive behavior were malleable (Dolan et al., 1993; Kellam, Rebok, Ialongo et al., 1994; Kellam, Rebok, Mayer, et al., 1994). More specifically, ML resulted in significant improvement in academic performance by the end of first grade, whereas the GBG resulted in significant reductions relative to controls in aggressive and disruptive behaviors based on teacher ratings and peer nominations in first grade.

Overview of the Rationale and Design of the Johns Hopkins Preventive Intervention Research Center Trials: The Second-Generation Trial

Although promising, the immediate results of the first-generation trial raised a number of questions; thus the reason for the second-generation trial. In this second-generation field trial, the two classroom-based interventions used in the first-generation JHU PIRC trial were revised to enhance their effectiveness. The revised intervention protocol included a specific focus on reducing off-task behavior and improving academic performance. The revised protocol also featured a focus on both aggressive disruptive behavior and academic performance. The decision to focus on

both academic performance and aggressive disruptive behavior was driven by the evidence from the 1985 to 1986 trial that whereas ML had a beneficial impact on early academic performance, it had only a modest to moderate crossover, or indirect, effect on aggressive disruptive behavior. Similarly, the GBG had a beneficial impact on aggressive and shy behavior, but not on academic performance. Each intervention thus appeared to be specific to its proximal target. Consequently, to reduce the later risk for substance abuse, depression, and antisocial behavior, both early aggressive disruptive behavior and academic performance needed to be targeted.

In addition to combining the two classroom interventions for this second-generation intervention trial, a universal, family-school partnership (FSP) intervention was developed and fielded to contrast with the combined classroom intervention. Like the classroom-centered intervention, the proximal targets of the FSP intervention were poor academic performance and aggressive disruptive behavior. The FSP intervention sought to reduce these early risk behaviors by enhancing family-school communication and parenting practices associated with learning and behavior. The decision to develop a family-based intervention component was consistent with existing theory and the considerable empirical evidence of the important influences that families exert on their children's academic success (Gallagher, 1987; Rutter, 1985; Scott-Jones, 1984; Sines, 1987) and social development (Kazdin, 1985; Patterson, Reid, & Dishion, 1992) and the benefits of strong parent-teacher partnerships and parent involvement (Henderson, 1987; Sattes, 1985) on children's behavior and achievement. The addition of a family-based component also was consistent with the pioneering work of Hawkins and his colleagues (1992) in Seattle and Reid, Eddy, and Fetrow (1999) at the Oregon Social Learning Center; in both sites, the feasibility and effectiveness of a universal family component, along with classroom-based preventive efforts, were demonstrated in elementary school children.

The final design of this second-generation JHU PIRC trial thus involved the evaluation of two theory-based, first-grade, universal preventive interventions. One sought to reduce the early risk behaviors of poor academic performance and aggressive disruptive behavior through the enhancement of classroom curricula and teacher instructional and behavior management practices. The second sought to reduce these early risk behaviors by improving parent-teacher collaboration and by enhancing parents' teaching and behavior management skills.

A randomized block design was employed, with schools serving as the blocking factor. Three first-grade class-

rooms in each of nine urban elementary schools were randomly assigned to one of the two intervention conditions or to a control condition. As with the first-generation trial, teachers and children were randomly assigned to intervention conditions. A total of 678 children and their parents were available for the fall of first-grade pretest measures. The immediate impacts of the interventions are described in Ialongo, Werthamer, Brown, Kellam, and Wang (1999); the middle school outcomes are reported in a series of reports (Furr-Holden, Ialongo, Anthony, Petras, & Kellam, 2004; Ialongo, Poduska, Werthamer, & Kellam, 2001; Storr, Ialongo, Anthony, & Kellam, 2002).

The Conceptual Framework Guiding the Johns Hopkins Preventive Intervention Research Center First- and Second-Generation Trials

The JHU PIRC's conceptualizations of normal and pathologic development and, in turn, the choice of its preventive interventions and their proximal and distal targets have been guided by the *life course/social field* framework (Kellam & Rebok, 1992), as described earlier. This framework focuses on the measurement within epidemiologically defined populations of early maladaptive responses to social task demands that increase the risk of poor psychological well-being and mental and substance abuse disorders over the life course.

The integration of our life course/social fields framework and Patterson, Reid, et al.'s (1992) model of the development of antisocial behavior provides the theoretical basis for the JHU PIRC's understanding of normal and pathogenic development and the impact of the intervention components targeting the early antecedent risk behaviors of aggressive disruptive behavior and their distal correlates. According to Patterson and colleagues, there are at least two major pathways to substance use, antisocial behavior, and depression in adolescence. One—the *early starter* model—begins in the toddler years, when parents' success in teaching their child to interact within a normal range of compliance and aversive behavior is a prerequisite for the child's development of social survival skills. Alternatively, the parents' failure to effectively punish coercive behavior during these formative years and to teach reasonable levels of compliance constitutes the first step in a process that serves to train the child to become progressively more coercive and antisocial. In the classroom setting, such children prove difficult for teachers or peers to teach appropriate forms of social interaction and problem solving. Moreover, their coercive style may be further reinforced in the presence of inconsistent and coercive teacher

disciplinary practices. Ultimately, parents, teachers, and well-adjusted peers reject the coercive child, which results in the child's failure to develop academic, social, and occupational survival skills. That is, the opportunities to learn these skills through interaction with teachers, parents, and peers are greatly reduced due to the rejection.

Patterson, Reid, et al. (1992) argue that the lack of adequate monitoring by parents in early adolescence and rejection by teachers and mainstream peers precipitates "drift" into a deviant peer group, wherein a wide array of anti-social and delinquent behavior, including alcohol and drug use, may be reinforced, along with rejection of mainstream norms and mores (Brook et al., 1989; Hirschi, 1969; Jessor, 1978; Patterson, Reid, et al., 1992). The rejection of such norms and mores appears also to be associated with a higher likelihood of premarital sex and teenage pregnancy, child bearing, and parenthood (Capaldi, Crosby, & Stoolmiller, 1996). Concomitant with the drift into a deviant peer group, the opportunities for obtaining positive reinforcement from mainstream natural raters—such as, parents, teachers, and well-adjusted peers—are significantly reduced. In turn, the coercive youth will be more likely to use substances as a means of obtaining reinforcement and negating the reductions in reinforcement dispensed by mainstream natural raters. Relatedly, the lack of positive reinforcement received from mainstream natural raters may lead to decrements in psychological well-being (Capaldi, 1991, 1992), which the youth seeks to alleviate through substance use (Chen, Anthony, & Crum, 1999). In turn, the youth's substance use may lead to further failure in meeting the demands of the school, peer group, family, work, and intimate relationship social fields. In an escalating, cyclic fashion, these failures may lead to further decrements in psychological well-being and increased substance use, abuse, and dependence.

One potential mechanism by which substance use may undermine social adaptation is via attention/concentration problems and impulsivity, which may, in turn, undermine success in the classroom social field by reducing on-task time and disrupting the encoding of task-relevant information into memory (Rebok, Hawkins, Krener, Mayer, & Kellam, 1996). The attention/concentration problems and impulsivity associated with substance use may also contribute to increased aggressive behavior by disrupting the process of encoding social cues essential to social problem solving and conflict resolution with adults and peers (Crick & Dodge, 1994; Dodge, 1986).

Patterson, Reid, et al. (1992) offer a second model of the development of antisocial behavior, which seeks to explain the relatively high prevalence of late-onset (i.e., in the pre-

or early adolescent years) antisocial behavior and substance use. Patterson, Reid, et al. argue that the *late starters* typically exhibit marginal levels of social adaptation in the elementary school years in terms of aggressive disruptive behavior and the development of social survival skills. Moreover, their caregivers' discipline and monitoring skills may be marginal at best. Consequently, these children are quite vulnerable to perturbations in parental monitoring and supervision, which may lead to rapid escalation of behavior and/or academic achievement problems. More specifically, Patterson, Reid, et al. hypothesize that the escalation in antisocial behavior seen in these late starters in early adolescence is the product of disruptions in parental monitoring and supervision, brought on by serious family adversities that first surface in the middle school years and tend to be chronic in nature. The disruptors include divorce, serious financial distress associated with the loss of a job, and the late onset of parental psychiatric distress or substance use, abuse, or dependence. Like the early starters, these late-onset children are then rejected by their mainstream natural raters as a result of their coercive and antisocial behavior. Their limited social survival skills and the rejection by their mainstream natural raters then precipitate drift into a deviant peer group, where antisocial behavior, substance use, and rejection of mainstream social values, mores, and institutions are reinforced.

In keeping with the JHU PIRC's life course/social fields framework and its integration with Patterson, Reid, et al.'s (1992) early starter model, the JHU PIRC's interventions were hypothesized to reduce the early aggressive disruptive behavior and its distal correlates in the following manner:

1. The interventions should improve teachers' and parents' disciplinary practices, which should then result in a reduction of early aggressive and coercive behavior at the level of the youth and the classroom.
2. As a result of the reduction in aggressive behavior at the level of the classroom, there should be fewer opportunities for the youth to learn inappropriate behavior through modeling of classmates' aggressive behavior.
3. The youth should then be at decreased risk of being rejected by parents/caregivers, teachers, and peers.
4. Parents should be more likely to monitor and supervise their child and engage in jointly reinforcing activities with him or her.
5. The youth should be less likely to drift into a deviant peer group, where substance use and antisocial behavior may be reinforced and mainstream norms and mores

rejected, including those around pre-marital sex and teenage pregnancy, child bearing, and parenting (Brook et al., 1989; Hirschi, 1969; Jessor, 1978).

6. Ultimately, the youth should be less likely to fail in the classroom, in family, peer, and intimate relations, and in the work social fields in adolescence and early adulthood.
7. The youth should be at reduced risk for decrements in psychological well-being.
8. The youth should be at reduced risk for early and sustained substance use, given the high level of psychological well-being and the ample opportunities for positive reinforcement from mainstream natural raters.
9. The lower the risk of substance use, the more likely the youth will successfully meet the demands of the school, peer group, family, work, and intimate/romantic relationship social fields.
10. Consequently, psychological well-being should be high.

As noted earlier, Patterson, Reid, et al. (1992) posit a second, or late starter, pathway to substance use and antisocial behavior, which begins in the pre- to early adolescent years. Their late starter model centers on disruptions in parental supervision and discipline during the late childhood and early adolescent years among parents with marginal parenting skills. The disruptions may be brought on by events such as a divorce, parental illness, unemployment, or spousal conflict. With respect to the late starter model and mechanisms of intervention impact, it was hypothesized that the family-school partnership intervention would enhance the parenting skills of those parents with marginal as well as those with poor parenting skills in first grade. Thus, the parenting skills of those parents in the FSP intervention would be less likely to be disrupted in the later childhood and early adolescent years by adverse life events. In turn, relative to standard-setting youth, FSP youth would be less likely to develop antisocial behavior and drift into a deviant peer group, where antisocial behavior, substance use, and rejection of mainstream social values, mores, and institutions are reinforced. These FSP youth would also have higher levels of psychological well-being given that they would be less likely to be rejected by parents, teachers, and mainstream peers and more likely to be reinforced for success in the academic/school, peer group, and family social fields.

In terms of the classroom-based interventions and the late starter model, youth with marginal skills in the academic, conduct/behavioral, and peer relations domains prior to the intervention would have higher levels of social adaptation in these domains over the childhood and adoles-

cent years relative to their standard-setting counterparts. Consequently, the youth who participated in the classroom-based interventions would maintain higher levels of social adaptation in the face of disruptions in parent supervision, discipline, and reinforcement in the pre- to early adolescent years than their standard-setting counterparts. As a result, these youth would be less likely to drift into a deviant peer group and engage in serious antisocial behavior and heavy substance use and abuse. Moreover, due to their success in the academic/school, peer group, and family social fields, these youth would have higher levels of psychological well-being than their standard-setting counterparts.

The JHU PIRC interventions were hypothesized to reduce the early antecedent risk behavior of poor achievement, its distal correlates, and the corresponding need for and use of youth mental health and special education services in the following manner:

1. The interventions should improve teachers' and parents' instructional practices and parent support and involvement for children's academic achievement.
2. Youth achievement should then improve, along with the classroom's overall level of achievement.
3. As a result of the overall improvement in classroom academic achievement, there will be a greater number of academically successful youth in the classroom for their classmates to model, which may result in increased academic effort and achievement.
4. Success in the achievement domain over the elementary school years should result in greater perceptions of personal control and increased perceived competence in the scholastic domain during the middle and high school years.
5. These successes should set the stage for improved psychological well-being and success in meeting the demands of the postsecondary education and work social fields.
6. Relatedly, youth who succeed academically should be less likely to engage in disruptive and off-task behavior, which should then reduce the risk of their being rejected by teachers, parents, and peers.
7. Consequently, these youth may be more likely to develop the social survival skills necessary for success in the school, peer group, family, and work social fields.
8. Thus, they would be at reduced risk for decrements in psychological well-being.
9. These youth would also be at reduced risk for early and sustained substance use, given their high level of psychological well-being and the ample opportunities for

positive reinforcement from their mainstream natural raters.

10. The lower the risk of substance use, the more likely these youth will be successful in meeting the demands of the school, peer group, family, work, and intimate relationship social fields.
11. They also will be less likely to drift into a deviant peer group, where substance use and antisocial behavior may be reinforced and mainstream norms may be rejected (Brook et al., 1989; Hirschi, 1969; Jessor, 1978; Patterson, Reid, et al., 1992).

ILLUSTRATIVE EXAMPLES OF UNIVERSAL PREVENTIVE INTERVENTION TRIALS AS TESTS OF DEVELOPMENTAL THEORY

Theoretical models of the development of antisocial behavior have proposed distinct pathways leading to criminal activity. Petras et al. (2003) used general growth mixture modeling (GGMM) to find empirical evidence for these pathways in the first-generation JHU PIRC participants. Petras et al. also examined the relationship between these pathways and later outcomes, including Conduct Disorder, Antisocial Personality Disorder, juvenile arrest, and adult incarceration. We offer the findings from Petras et al. as an example of a test of the link between early and later adaptation, consistent with a major tenet of the life course/social fields framework and the organizational theory of development.

Data for Petras et al. (2003) were gathered in the fall and spring of first and second grades, the spring of third through seventh grades, and at an age 19 to 20 follow-up assessment. The data gathered in the first through seventh grade assessments included teacher reports of child aggressive disruptive behavior and free lunch eligibility. At the age 19 to 20 follow-up, a structured clinical interview was used to ascertain whether the participant met criteria for Antisocial Personality Disorder (ASPD).

The statistical methods used in Petras et al. (2003) were consistent with a person-centered approach to data analysis, which emphasizes individual differences in development (Bergman & Magnusson, 1997). GGMM (Muthén & Muthén, 2000), as implemented in the Mplus Version 2 statistical software package (Muthén & Muthén, 1998), was used to identify distinct patterns of growth in aggressive disruptive behavior over time. Like traditional growth modeling techniques, GGMM estimates latent variables based on multiple indicators. The multiple indicators of latent growth parameters correspond to repeated univariate outcomes at

different time points. However, rather than assuming that the population is constructed of a single continuous distribution, GGMM tests whether the population is constructed of two or more discrete classes (pathways) of individuals, with the goal of determining optimal class membership for each individual. Evidence for these different pathways in aggressive disruptive behavior exists when models involving two or more latent classes of growth provide a better fit than a traditional single-class growth model.

GGMM is similar to the semiparametric group-based (SPGB) modeling approach described by Nagin (1999) in that classes define different trends over time in repeated measures (Muthén, 2000). However, unlike SPGB, GGMM allows for the modeling of class-specific levels of variation. For models in which all parameters are the same, GGMM and SPGM provide identical results. GGMM was selected to allow for the possibility of heterogeneity within classes as it did not seem reasonable to assume that all youth within a given class would have identical patterns of aggressive behavior. Allowing for heterogeneity also tends to improve overall model fit and classification accuracy (Muthén, 2000). The observed time variant indicators consisted of teacher-rated classroom aggressive disruptive behavior measured at 9 time points: fall and spring of first grade, fall and spring of second grade, and spring of third through seventh grades.

The GGMM analyses in Petras et al. (2003) revealed three distinct high-risk trajectories for males (see Figure 24.1): start high and remain high, start low and increase in aggressive disruptive behavior over elementary school, and start low and stay low in aggressive disruptive behavior. These growth trajectories were largely consistent with Patterson, Reid, et al.'s (1992) early and later starter models of antisocial behavior. Males in the start high and remain high and increasing trajectories were at increased risk for

Figure 24.1 General growth mixture model for males based on teacher rated aggressive disruptive behavior from grades 1 to 7 and an antisocial personality diagnosis at age 19–20.

Figure 24.2 General growth mixture model for females based on teacher rated aggressive disruptive behavior from grades 1 to 7 and an antisocial personality diagnosis at age 19–20.

ASPD in young adulthood (see Figure 24.1). Of importance, Petras et al. found a similar set of early aggressive disruptive behavior pathways among girls in the first-generation JHU PIRC data. As with the boys, these early pathways were highly predictive of later ASPD in young adulthood (see Figure 24.2).

These findings provide strong support for the posited link between early and later social adaptation consistent with the life course/social fields framework and the organizational theory of development. However, Petras et al. (2003) also carried out an experimental test of the hypothesized causal relationship between early and later social adaptation, utilizing the GBG intervention and control group participants. In a first step in their analysis, Petras et al. assessed the impact of the GBG intervention on growth of aggressive disruptive behavior within each class or aggressive disruptive behavior trajectory class. More specifically, Petras et al. examined the effect of the GBG intervention on the slope parameter within each of the trajectory classes. The slope represents the shape of the growth process within each trajectory class. The comparison or standard setting (control) classrooms for this analysis were those standard setting classrooms in schools that included GBG classrooms. For males, Petras et al. found a significant impact of the GBG intervention on the slope of aggressive disruptive behavior in the start and remain high aggressive disruptive behavior trajectory. In contrast to GBG control males, the slope for GBG intervention males showed a significantly greater decline in the rate of growth of aggressive disruptive behavior. In addition, the GBG intervention males in this start high and remain high aggressive disruptive behavior trajectory class had a significantly lower rate of ASPD at the age 19 to 20 follow-up interview.

One of the questions that remained was whether the impact of the GBG on ASPD at age 20 to 21 was mediated via the GBG's impact on the early growth of aggressive disruptive behavior. Consistent with Baron and Kenny (1986), to demonstrate mediation one must first establish that the independent variable is statistically associated with the mediator and the outcome and that the mediator is significantly associated with the outcome. One must then show that after controlling for the effect of the intervention on the mediator, the direct effect of the independent variable on the outcome should no longer be significant and that the change in the size of the estimate of the direct effect should be statistically significant. However, a straightforward test for mediation in the GGMM framework is not presently possible. The distal outcome in growth mixture modeling is regressed on the categorical variable representing class membership and not the within-class growth parameters (intercept and slope). Moreover, the goal in growth mixture modeling is to derive classes with limited within-class variance in terms of the growth parameters (intercept and slope). Consequently, if one wished to test for mediation using the within-class slope as a mediator, intervention condition as the independent variable, and ASPD as the outcome, it is likely that slope variance would be too small to provide an adequately powered test of mediation.

In the absence of an established method to test for mediation consistent with Baron and Kenny (1986), Petras et al. (2003) employed what can be best described as an approximation of the Baron and Kenny method. Their approximation involved the use of the likelihood ratio test to compare competing models. More specifically, Petras et al. constrained the path from the GBG intervention condition to the slope within the start and remain high aggressive disruptive behavior class to zero. Petras et al. then compared the log likelihoods between the latter model and one where the path from the GBG intervention condition to the slope was freely estimated. The difference was not significant, suggesting that the impact of the GBG intervention on ASPD in males was not mediated through its impact on the slope of aggressive disruptive behavior in the start high and remain high growth trajectory. However, as pointed out earlier, this is at best an approximation of the test for mediation offered by Baron and Kenny, given that one cannot truly test for mediation in the growth mixture modeling framework. Nevertheless, although an approximation, the model fit worsened when the path between the intervention condition and the slope of aggressive disruptive behavior within the start high and remain high aggressive behavior growth trajectory was constrained to zero. The worsening in fit was consistent with the expectation that the impact of

the GBG on the distal outcome of ASPD was via its impact on the growth of aggressive behavior in elementary school.

One explanation for failure to find a significant difference between model fits may simply be that the sample size was too small to detect a difference. As MacKinnon, Lockwood, Hoffman, West, and Sheets (2002) point out, tests of mediation in the social sciences are often underpowered, not only due to sample size, but as a result of the joint distributions of the independent, mediator, and outcome variables. In the case of growth mixture modeling, this issue is amplified due to the fact that the object of growth mixture modeling is to account for the variance in the growth of the mediator via the assignment of individuals into trajectory classes based on similarities in their growth parameters: intercept and slope.

Petras et al. (2003) also examined the effect of the GBG on the increasing and stable low aggressive disruptive behavior growth trajectories among males (Figure 24.1). No effect was found for the GBG on the slope of aggressive disruptive behavior in the increasing class or in the stable low class. The absence of an effect on the slope of the low class was not surprising as it was close to zero; consequently, there was virtually no room for improvement. With regard to the increasing or late starter class, the hypothesis that the GBG would protect youth from the effects of disruptions in parenting in the late childhood and early adolescent years via improvement in social adaptation in the early elementary school years was not supported. Of note, the growth of aggressive disruptive behavior showed a precipitous rise after the completion of the intervention in aggressive disruptive behavior at the end of second grade and the beginning of second grade. Thus, it may be that the intervention suppressed the growth of aggressive disruptive behavior during the period that the intervention was in place, but once the systematic classroom behavior management practices associated with the GBG were no longer in place, those individual, family, classroom, and/or peer group factors hypothesized by Patterson, Reid, et al. (1992) to play a role in their late starter model may have overcome any benefits of the GBG.

Finally, Petras et al. (2003) studied the effects of the GBG on females (Figure 24.2). In general, the pattern of results was consistent with the effects of the GBG on males, such that the most beneficial effects were seen in the high aggressive behavior trajectory. However, unlike the males, the effects of the intervention did not prove statistically significant, either in terms of the impact of the GBG on the growth of aggressive disruptive behavior in the high aggressive disruptive behavior growth trajectory class or on the distal outcome. The most likely explanation for the lack of significant intervention effects for females relative to males was that the number of females in the high aggressive

disruptive behavior trajectory was substantially lower—about 50%—than among males. Consequently, the statistical power to detect significant effects was likely lower.

To summarize, Petras et al. (2003) found evidence to support a major premise of the life course/social fields framework and organizational theory of development: Success or failure at later stages of development may be a function in part of success or failure at early stages of development. More specifically, Petras et al. found that children who exhibited either a high or increasing course of aggressive disruptive behavior over the elementary school years were at significantly higher risk of antisocial outcomes in early adulthood, in contrast to those who exhibited a stable low level of aggressive behavior. This finding held for both males and females. In addition, Petras et al. demonstrated a significant and beneficial impact of the GBG intervention on both the growth of aggressive disruptive behavior among boys in the start high and remain high trajectory class and the distal outcome of ASPD. This suggests that early aggressive behavior may be malleable and, in turn, that a reduction in the growth of aggressive disruptive behavior among boys in the start high and remain high growth trajectory may translate into later reductions in antisocial behavior in young adulthood. In the absence of a formal test of mediation in the growth mixture modeling framework, Petras et al. could not conclude, however, that the GBG effect was mediated through its impact on the early growth of aggressive disruptive behavior. A formal test of mediation in the growth mixture framework awaits further development. The absence of an effect of the GBG on growth of aggressive disruptive behavior among females in Petras et al.'s study was likely due to insufficient statistical power and not a differential impact of the GBG, given that the pattern of intervention effects were similar to those seen in boys. The fact that there were fewer females than males in the start high and remain high growth trajectory may account for the failure to find a statistically significant intervention impact for females. In general, the data from Petras et al. suggest the need for much larger samples when evaluating the impact of universal preventive interventions such as the GBG, given that the benefits of such universal interventions are likely to be seen only in those individuals evidencing some elevation in risk.

A Test of the Link between the Initiation of Substance Use and Early and Later Adaptation to the Developmental Demands of the Classroom

As described, Petras et al. (2003) illustrated the use of GGMM to test Patterson, Reid, et al.'s (1992) theory of early and late starter growth trajectories of aggressive disruptive behavior and the development of ASPD among males

and females. Using data from the second-generation JHU PIRC trial, we present an example where we replicate and extend Petras et al.'s study to include the influence of class membership—with respect to the growth of aggressive disruptive behavior over grades 1 to 3—on survival to first use of marijuana. The focus on survival to first use is consistent with evidence that early use may predict later use (Brunswick, Messeri, & Titus, 1992; Kandel & Davies, 1992), particularly heavy use. In this example, we also employed parallel and sequential growth mixture modeling to test the moderating influence of peer rejection on the growth of aggressive disruptive behavior in grades 1 to 3 and their joint influence on the growth trajectories of conduct problems in grades 6 to 9. This is in keeping with Patterson, Reid, et al.'s theory that high levels of aggressive disruptive behavior and peer rejection in the elementary school years would be associated with high levels of conduct problems in the adolescent years and the early onset of drug use.

The goal of this example is to illustrate how one can use parallel and sequential process GGMM to understand the moderating influences of child, family, peer group, school, and neighborhood/community variables on the classes of growth of early and later aggressive disruptive behavior and survival to substance use. Of course, the number of constructs one can examine within these parallel and sequential process models is limited by sample size and, relatedly, the statistical power to detect differences between classes with respect to the distal outcomes of interest. As such, we examine here a small subset of moderators within the GGMM framework, beginning with the subset with the strongest theoretical and empirical evidence of their importance.

The first step in this parallel and sequential process GGMM analysis involved carrying out a separate GGMM analysis for both teacher-rated aggressive disruptive behavior and peer rejection in grades 1 to 3, and for teacher-rated conduct problems in grades 6 to 9. We confine this analysis to males given the relatively low frequency of marijuana use in girls by grade 9 and the resulting reduction in statistical power. The separate GGMM analyses yielded three classes, or growth trajectories (high, increasing, and low), for aggressive disruptive behavior in grades 1 to 3, two classes (high and low) for peer rejection in grades 1 to 3, and three classes for conduct problems in grades 6 to 9 (high, increasing, and low).

In the second step, we created 18 classes, or growth trajectories, for the parallel and sequential process component of the analysis (based on the total number of possible unique combinations of aggressive disruptive behavior, peer rejection, and conduct problem classes established in Step 1). The growth parameters used in the modeling of these 18 classes were drawn from the separate GGMM analyses in

the first step. For example, the growth parameters for the class representing those participants who were high on aggressive disruptive behavior, peer rejection, and conduct problems were drawn from the high classes found in the separate GGMM analyses carried out in Step 1. The 18 class parallel and sequential process GGMM model failed to converge, owing to the number of classes with too few participants to estimate the necessary model parameters. This was an expected finding from a substantive standpoint. For example, given theory and empirical evidence, we thought it unlikely that we would see a class that featured participants who were high on aggressive disruptive behavior and low on peer rejection in grades 1 to 3—which proved to be the case. Ultimately, a model featuring six classes converged and yielded acceptable model fit indices.

In the third and final step, survival to first use of marijuana was incorporated into the model in accord with Muthén and Masyn (2005). This model allowed us to examine whether survival to first use of marijuana varied across the six classes found in the sequential and parallel process GGMM analysis. Although preliminary, the results suggested that the key to survival to first use of marijuana—at least through entrance to high school—was the growth of conduct problems in grades 6 to 9. Specifically, those classes containing participants demonstrating an increasing or a steadily high trajectory of conduct problems in grades 6 to 9 demonstrated the lowest rates of survival to first use of marijuana, and the highest survival rates were found in the classes with low levels of conduct problems in grades 6 to 9. This is not to suggest that high levels of aggressive disruptive behavior and peer rejection are not of importance to survival to first onset of marijuana use, but rather that increasing or high levels of conduct problems in grades 6 to 9 must be present as well, which is consistent with Patterson, Reid, et al.'s (1992) model. Indeed, it is important to note that the odds of being in the high class of conduct problems in grades 6 to 9 was significantly higher for those participants in the high class of aggressive disruptive behavior in grades 1 to 3 relative to their counterparts in the low class.

ILLUSTRATIVE EXAMPLES OF SELECTIVE/INDICATED PREVENTIVE INTERVENTION TRIALS AS TESTS OF DEVELOPMENTAL THEORY: MOUNT HOPE FAMILY CENTER, UNIVERSITY OF ROCHESTER

Although many risk factors for the development of maladaptation and psychopathology have been identified, longitudinal correlational research has demonstrated some

specific risk conditions that carry substantial burden for the developing individual. These risk factors present unique challenges to children and families and are not likely to be sufficiently altered by broad-based universal interventions. For example, parental divorce or loss of a parent through death results in major disruptions in family life, parental distress, high potential for conflictual parent-child relationships, and additional stressors, such as income loss. To address the negative consequences of these atypical life events, preventive interventions tailored to the unique experiences of such families are necessary (Sandler et al., 2003; Wolchik et al., 2002).

Other risk factors involve family contexts with negative effects that are more pervasive and pernicious. For example, child maltreatment involves extreme family dysfunction, posing severe impediments to competent child development. Extensive, deleterious sequelae of child maltreatment on psychological and biological functioning have been enumerated, and the maltreated child is at high risk for the emergence of diverse forms of psychopathology. Parental mental illness, such as depression, Schizophrenia, and alcohol and substance abuse, confers risk on children through compromised parenting, difficulties in parent-child relationships, and marital discord, as well as potential genetic vulnerabilities. The risk processes involved in child maltreatment and parental mental illness may extend from the prenatal period onward. Thus, preventive interventions occurring early in the life course are indicated, given the early signs of nonoptimal development that may begin to unfold. In this section, we focus our discussion of targeted preventive interventions on two potent risk factors, child abuse and neglect and maternal depression, with illustrations provided by preventive trials conducted at Mt. Hope Family Center, University of Rochester.

The organizational perspective on development, as discussed earlier, forms the foundation for formulating early interventions to address these risk conditions. At each stage of development, the individual is confronted with central age- and stage-relevant challenges or tasks. Competent resolution of each of these developmental tasks promotes better preparedness to adapt to subsequent developmental challenges, whereas incompetent resolution may engender compromised capacities to adapt successfully. As each stage-salient issue emerges, it remains important to adaptation henceforth, and the quality of the developmental task resolution is consolidated and integrated across biological and psychological systems. Through progressive reorganization as the individual develops, different pathways unfold, varying in degree of developmental competence versus maladaptation. Continuity in development is preserved through the ongoing processes of differentiation

and hierarchic integration. However, based on new experience, developmental divergence and discontinuity also are possible. From this perspective, psychopathology evolves as a result of an integration of incompetent developmental structures across biological and psychological systems, or as a lack of integration across systems.

From this perspective, child abuse and neglect and maternal depression occurring early in the life course confront the developing child with a family and relational environment that does not support the successful resolution of stage-salient developmental tasks. Accordingly, over the early years of development, these risk factors set in motion a progression of compromised developmental attainments that generate vulnerabilities in the organization of developmental systems. As a result, children reared under these conditions are liable to develop diverse forms of psychopathology. To combat this progression, the preventive strategy involves early interventions to instill competence on stage-salient developmental tasks to direct children onto adaptive developmental trajectories.

Effects of Child Maltreatment during Infancy

Extensive evidence exists documenting the deleterious effects of child maltreatment on developmental systems across the life course (Cicchetti, 2002; Cicchetti & Lynch, 1995; Cicchetti & Toth, 2000; DeBellis, 2001; Trickett & McBride-Chang, 1995). In focusing on the early years of life, we briefly highlight findings related to difficulties in affect regulation, attachment, and self-development.

In terms of early affect differentiation, maltreated infants have been observed to display four atypical patterns: developmentally and affectively retarded, depressed, ambivalent/affectively labile, and angry (Gaensbauer, Mrazek, & Harmon, 1981). Physically abused infants were more likely to exhibit restricted positive affect and high negative affect, including fear, anger, and sadness, whereas neglected infants appeared affectively blunted. Beyond infancy, maltreated children have been found to have a selective bias and sensitivity toward the detection of anger (Camras et al., 1990; Pollak, Cicchetti, Hornung, & Reed, 2000) and are hypervigilant to aggressive stimuli (Rieder & Cicchetti, 1989). Psychophysiological studies have further demonstrated via event-related potentials (ERPs) that maltreated children evince a differential processing of emotion stimuli that is specific to anger (Pollak, Cicchetti, Klorman, & Brumaghim, 1997; Pollak, Klorman, Thatcher, & Cicchetti, 2001; Pollak & Tolley-Schell, 2003). Patterns of emotion dysregulation in response to interadult anger have been found among preschool-age maltreated children

(Maughan & Cicchetti, 2002), and school-age maltreated children evince attenuated emotion regulation in the form of emotional lability/negativity and inappropriate affect in interactions with their peers (Shields & Cicchetti, 2001).

The development of an attachment relationship with the primary caregiver allows the infant to maintain internal security while beginning to explore the environment. Sensitive and responsive maternal care is associated with secure attachment relationship formation, whereas inconsistent, intrusive, and rejecting care contributes to varied forms of insecure attachments. Among maltreated infants, high rates of insecure attachment (i.e., two-thirds avoidant or resistant) have been observed (Egeland & Sroufe, 1981; Schneider-Rosen, Braunwald, Carlson, & Cicchetti, 1985). Moreover, in studying maltreated infants, considerable difficulty in classification routinely occurred because of the frequency of many atypical and unusual attachment behaviors. As a result of this observation, patterns of disorganized/disoriented attachment were identified (Main & Solomon, 1986, 1990). Another atypical pattern detected involved infants exhibiting both avoidant and resistant attachment behaviors (Crittenden, 1988). When the attachment behavior of maltreated infants was reevaluated with the inclusion of the disorganized and avoidant-resistant patterns, insecure attachment classifications were found for as many as 90% of maltreated infants, with 80% showing the atypical, disorganized patterns (Barnett, Ganiban, & Cicchetti, 1999; Carlson, Cicchetti, Barnett, & Braunwald, 1989; Lyons-Ruth, Repacholi, McLeod, & Silva, 1991). As development proceeds, children form representational models of attachment figures, the self, and the self in relation to others (Bowlby, 1969, 1982; Bretherton, 1985; Crittenden, 1990). These representational models organize affect, cognitions, and behavior and serve as guides for later interpersonal behavior in subsequent relationships (Sroufe & Fleeson, 1986, 1988). Thus, for maltreated infants, highly insecure representational models are likely to evolve, boding poorly for later relationship experiences.

Because insecure and disorganized attachment relationships are almost universally observed among maltreated infants, the development of an autonomous self during the toddler period is likely to be impaired. Although the cognitive capacity for visual self-recognition emerging during this period is not delayed among maltreated children, they do differ in the affect they exhibit when regarding the self, with more frequent negative or neutral affect, rather than the positive affect more commonly shown by nonmaltreated youngsters (Schneider-Rosen & Cicchetti, 1984, 1991). Other early self-system deficits also have been discovered, including a restricted ability to talk about themselves and

their internal states (Beeghly & Cicchetti, 1994; Coster & Cicchetti, 1993). Allesandri and Lewis (1996) have shown that maltreated children show atypical patterns of self-conscious emotion expression, with maltreated girls showing heightened shame and low levels of pride and maltreated boys exhibiting limited self-conscious emotions generally. Toth and colleagues have shown that maltreated preschool-age children, particularly those who were physically abused, had more negative self-representations (Toth, Cicchetti, Macfie, & Emde, 1997), and longitudinally, increases in grandiose self-representations were observed (Toth, Cicchetti, Macfie, Maughan, & VanMeenan, 2000). Evidence for the development of a "false self" (Koenig, Cicchetti, & Rogosch, 2000) and delays in theory of mind development (Cicchetti, Rogosch, Maughan, Toth, & Bruce, 2003) further attest to early difficulties that maltreated children have in the development of an adaptive self-system.

This sampling of research indicates that children maltreated early in life already exhibit signs of compromised developmental competencies on early stage-salient tasks. Consequently, these liabilities contribute to the emergence of developmental pathways that are likely to be progressively maladaptive and conducive to the development of varied forms of psychopathology. Preventive intervention thus must alter these trajectories through reducing ongoing risks and promoting protective processes. When maltreatment has already occurred, efforts to prevent further maltreatment are crucial, and intervening to reduce sources of dysfunctional parenting and parent-child relationships is central to this goal.

Many parents in maltreating families experienced child maltreatment in their own family of origin; as a result, the risk for intergenerational transmission of maltreatment with one's own children is heightened, yet not inevitable (Kaufman & Zigler, 1989). For parents who endured maltreatment as children, understanding and relating to children sensitively and responsively may be difficult, given the lack of experience in benign parent-child relationships. Research with maltreating parents has identified affective, cognitive, and behavioral deficits and atypicalities that conspire to undermine appropriate caregiving and responsiveness to children's evolving emotional and physical needs (Azar, 2002; Rogosch, Cicchetti, Shields, & Toth, 1995). Such parents lack effective parenting skills and general knowledge of child development, have difficulty relating affectively to their children, and misread and misinterpret their children's behavior and emotional expression. Furthermore, as a result of maltreatment during childhood and other problematic parent-child relationship experiences, many maltreating parents have insecure internal representational models of self and of

attachment relationships (Crittenden & Ainsworth, 1989), and these models intrude on their ability to relate to their children and provide "good enough care" (Winnicott, 1958). Insecure representational models also contribute to conflict and instability in adult relationships. Coupled with poverty, single parenthood, and myriad associated stressors, maltreatment may occur as multiple risk factors overwhelm limited protective resources (Cicchetti & Lynch, 1995).

Randomized Prevention Trials for Child Maltreatment

Two models of preventive intervention, psychoeducational home visitation (PHV) and infant-parent psychotherapy (IPP), were evaluated in a randomized prevention trial to determine whether they would be efficacious in reducing the risk for further maltreatment, improving parenting, and fostering adaptive parent-child relationships, and as a result altering the developmental trajectories of 1-year-old maltreated infants. Given the centrality of attachment during this developmental period, establishing a secure attachment relationship was the targeted intervention outcome.

An agreement for a recruitment liaison was established with the local Department of Human and Health Services (DHHS). Because the liaison was an employee of DHHS, she was able to access DHHS and Child Protective Service (CPS) records to identify all infants in families where maltreatment had occurred. The liaison approached potential participants meeting inclusion criteria and explained the study; if interested, families signed a consent authorizing their names to be released to the project. Families were assessed at baseline when infants were 12 months of age, and follow-up postintervention assessments were conducted at age 26 months.

In addition to the two active interventions, a community standard (CS) group also was included in the study design. The CS group received standard care available in the community. This typically involved monitoring by CPS but may have included referral to other community programs. Mothers in the PHV and IPP groups also were able to receive any standard community services. Following completion of the baseline assessments, mother-infant dyads were randomly assigned to the PHV, IPP, and CS groups. In addition to the three maltreatment groups, the DHHS liaison also recruited a nonmaltreated comparison (NC) group from the population of families receiving Temporary Assistance to Needy Families but with no history of child maltreatment. This strategy allowed for the inclusion of a normative comparison group that was comparable in terms of socioeconomic characteristics to the maltreating families.

Psychoeducational Home Visitation

This model of preventive intervention is derived from the work of Olds (Olds et al., 1997, 1998; Olds & Kitzman, 1990), involving visitation by nurses to the homes of low-income, teenage mothers of newborns over a 2-year period. The nurses provided a home-based education program on infant physical and psychological development and parenting, encouraged mothers to seek further education and employment, and enhanced informal social support. The home visitation program was effective in reducing the emergence of child maltreatment and fostered improved health and mental health outcomes for mothers and children. Although very promising, it is not known whether this approach is effective when maltreatment already had occurred during infancy. Accordingly, the PHV intervention was supplemented by a variety of cognitive and behavioral techniques to address parenting skill deficits and social-ecological factors, such as limited personal resources, poor social support, and stresses in the home, associated with maltreatment. Master's level therapists experienced in working with multiproblem families conducted home visits scheduled weekly over a 12-month period. The PHV model was psychoeducationally based, striving to address current concerns, provide parental education and parenting skill training, reduce maternal stress, foster social support, and increase life satisfaction. The approach is didactic in nature, providing mothers with specific information and knowledge regarding child development. Training in parenting techniques, problem solving, and relaxation was utilized. Within a core agenda of topics on parenting and social skills to be addressed with all mothers, flexibility and latitude on the amount of time spent on each area were stressed to tailor the intervention to each mother's primary needs.

Infant-Parent Psychotherapy

This model of intervention is derived from the work of Fraiberg (Fraiberg, Adelson, & Shapiro, 1975) and has been shown to be efficacious in fostering secure attachment in high-risk, low-income, immigrant families (Lieberman, 1991, 1992; Lieberman & Pawl, 1988). A guiding assumption of IPP is that difficulties in the parent-infant relationship do not result from deficits in parenting knowledge and skill alone. Rather, the problems that maltreating mothers have in relating sensitively and responsively to their infants stem from insecure internal representational models that evolved in response to the mother's own experiences in childhood. The infant evokes affects and memories associated with the mother's childhood relationship experiences, and in the process, the mother's unresolved

and conflictual feelings can be projected onto the infant, resulting in distorted perceptions of the infant, a lack of attunement, and insensitive care.

In IPP, the patient is not the mother or the infant; rather, it is the relationship between the mother and her baby. Master's level therapists met weekly with mothers and their 12-month-old infants during sessions conducted in the home over the course of 1 year. The approach is supportive, nondirective, and nondidactic and includes developmental guidance based on the mother's concerns. During the sessions, the therapist and the mother engage in joint observation of the infant. The therapist's empathic responsiveness to the mother and the baby allows for expansion of parental understanding and exploration of maternal misperceptions of the infant. Therapists strive to allow distorted emotional reactions and perceptions of the infant as they are enacted during mother-infant interaction to be associated with memories and affects from the mother's prior childhood experiences. Through respect, empathic concern, and unfailing positive regard, the therapeutic relationship provides the mother with a corrective emotional experience, through which the mother is able to differentiate current from past relationships and form positive internal representations of herself and of herself in relationship to others, particularly her infant. As a result of this process, mothers are able to expand their responsiveness, sensitivity, and attunement to the infant, fostering security in the mother-child relationship and promoting emerging autonomy in the child.

Both the IPP and PHV interventions were manualized, with central components and core principles of each approach specified. Therapists participated in individual and group supervision on a weekly basis, and checks on the fidelity of the intervention implementation for each approach were conducted throughout the course of intervention.

Program Outcomes

Consistent with prior research, mothers in the maltreatment groups compared to those in the nonmaltreatment group were found to differ substantially on important constructs expected to confer vulnerability on the mother's capacity to form a secure attachment relationship with her infant. In terms of the mother's own childhood history and her representation of her relationship with her own mother, maltreatment group mothers reported significantly more adverse childhood experiences than nonmaltreating mothers. Emotional and physical abuse and neglect as well as sexual abuse during childhood were reported more frequently among mothers in the maltreatment group. Fur-

thermore, maternal representations of the quality of their relationship in childhood with their own mother were marked by feelings of being unloved and highly rejected. In terms of current adult perspectives, maltreating mothers also derogated the importance of attachment and mother-child relationships and harbored considerable current anger toward their mother. The experiential and representational vulnerabilities forecast difficulties in the maltreatment group mothers in forming a sensitive and responsive relationship with their own infants.

In keeping with early relationship difficulties and current anger and resentment, mothers in the maltreatment group also reported less availability of social support from family members. Thus, the ability of these mothers to rely on family in times of need appears compromised. Maltreatment group mothers also reported significantly higher current stress. This stress was related to feeling more demands and struggles in relation to their child, as well as feeling less competent as a parent. Depression and health concerns also were more prominent stressors for these mothers. Contrary to expectations, the mothers in the maltreatment group did not convey deficits in their understanding of appropriate parenting attitudes and behavior, relative to nonmaltreating mothers. However, based on extensive observation, home observers who were unaware of group status rated mothers in the maltreatment group as substantially lower in maternal sensitivity to their infants than nonmaltreating mothers. Thus, histories of abuse and neglect in childhood, insecure relationship representations, limited family social support, stressors in multiple domains, and insensitive maternal patterns of relating to her infant likely conspire to impair secure attachment relationship formation.

During the baseline assessment at age 12 months, infant attachment organization was measured using the standard Strange Situation observation procedures. Videotapes were subsequently coded utilizing Ainsworth's (1969) criteria for the A, B, and C classifications; D classifications were based on the Main and Solomon (1990) criteria. The baseline attachment classifications indicated that the maltreated infants exhibited an extremely high rate of insecure attachment. In fact, only one infant in the maltreatment group (less than 1%) was classified as secure. The rate of secure attachment was substantially higher in the nonmaltreatment group (31.7%), yet below the rates observed in middle-class, nondisadvantaged samples. In terms of the specific insecure attachment organizations observed, not only were the maltreated infants rated as insecure, but nearly 90% were rated as disorganized, contrasting with 42.3% of the nonmaltreated infants. Thus, disorganized attachment was almost ubiquitous among the

maltreated infants. No differences in rate of insecure or disorganized attachment were observed among the three maltreatment groups.

Following the intervention, attachment organization was again assessed with the Strange Situation at age 26 months. Dramatic changes in attachment classification were observed. At follow-up, the rate of secure attachment had increased markedly in the two intervention groups to 60.7% and 54.5% for the IPP and PHV groups, respectively. In contrast, the rate of secure attachment in the CS group remained virtually nonexistent (1.9%). Moreover, the rate of secure attachment in the IPP and the PHV groups even surpassed the rate of security in the nonmaltreated group (38.6%). Thus, marked gains were achieved in establishing secure attachment organizations in both of the intervention groups. Change from insecure to secure attachment was significantly more likely in the IPP and PHV groups than in the CS and nonmaltreated control groups.

In contrast to the reorganization in attachment that had occurred in the intervention groups, stability of insecure attachment was almost universal in the CS group (98.1%). Similarly, stability of attachment also was more common in the nonmaltreated group, with 70.4% of the insecure nonmaltreated children remaining insecure at follow-up, and 53.9% of those who were secure remaining secure. Overall, stability of secure/insecure attachment was 63.7% in the nonmaltreated group. Thus, continuity of attachment organization was more characteristic of the groups not participating in the active preventive interventions.

Given the extremely high rate of disorganized attachment in the maltreated infants at age 12 months, it is remarkable that the two preventive interventions were efficacious in reducing this atypical attachment pattern. Stable disorganized attachment was observed among 74.1% of the CS children, whereas stable disorganized attachment occurred at much lower rates in the two intervention groups, 28.6% and 36.4% for the IPP and PHV groups, respectively, comparable to the rate observed in the nonmaltreated group, 27.3%. Thus, infants who have been maltreated are highly likely to maintain disorganized/disoriented attachments in the absence of intensive efforts to improve the mother-child relationship and parenting.

The results of the intervention provide strong support for the benefits of the preventive interventions in altering the developmental trajectories of maltreated infants. Through targeting a central developmental task of the infancy/toddler period, the interventions were successful in transforming the attachment organization of a substantial percentage of maltreated infants. Not only were marked reductions achieved in the rate of insecure attachment, but

disorganized attachments were shown to be modifiable and secure attachments were attained. These results are noteworthy for demonstrating the malleability and plasticity of the attachment system through focusing on changing aspects of the early mother-child relationship. The establishment of secure attachment relationships in the maltreated youngsters through the preventive interventions holds promise for achieving more competent resolutions of subsequent developmental tasks. In the context of a secure attachment relationship, the secure maltreated children are more likely to develop positive self-representations. Secure representational models of the self and self in relation to others will further promote competent striving to adapt to subsequent developmental challenges as these children begin forming relationships with other adults and peers. By intervening to promote more competent developmental trajectories through instilling a secure attachment organization, it is anticipated that maladjustment and the development of psychopathology will more likely be averted as these children develop.

Preventive Intervention for Maltreated Preschoolers: Preschooler-Parent Psychotherapy

The preschool years are a critical time for symbolic and representational development; therefore, this period provides an opportunity to help children with histories of child maltreatment avert difficulties with respect to their perceptions of self and their expectations about relationships with others. Because a considerable body of research has documented the deleterious effects of maltreatment on the representational development of abused and neglected children (Cicchetti & Toth, 2005), this population emerges as one that could benefit from targeted preventions.

Drawing from the extant literature, we implemented two interventions that shared the goal of improving attachment insecurity but that differed in the strategies utilized to attain this goal. These interventions were comparable to those utilized in the study of maltreated infants. Given the older age of the children, however, the IPP model of intervention was renamed preschooler-parent psychotherapy (PPP). In view of the importance of representational development, we assessed children's representations of self and of self in relation to others both prior to and following the provision of our preventive interventions.

At baseline and at postintervention, 11 narrative story stems, selected from the MacArthur Story-Stem Battery (Bretherton, Oppenheim, Buchsbaum, Emde, & the MacArthur Narrative Group, 1990) and from the Attachment Story Completion Test (Bretherton, Ridgeway, & Cassidy, 1990), were individually administered to child

participants. The narratives depicted moral dilemmas and emotionally charged events in the context of parent-child and family relationships. Narrative story stems included vignettes designed to elicit children's perceptions of the parent-child relationship, of self, and of maternal behavior in response to child transgressions, intrafamilial conflicts, and child accidents.

Children's narratives were videotaped and maternal and self-representations were subsequently coded according to the *MacArthur Narrative Coding Manual*, Rochester revision (Robinson, Mantz-Simmons, Macfie, & the MacArthur Narrative Working Group, 1992). A modified version of Bickham and Fiese's (1999) child narrative code book was utilized to assess expectations of the mother-child relationship (for details of these coding systems, see Toth, Maughan, Manly, Spagnola, & Cicchetti, 2002).

Children in the PPP intervention evidenced a greater decline in maladaptive maternal representations over time than did children in the PHV and CS interventions. Moreover, children who took part in the PPP intervention displayed a greater decrease in negative self-representations than did children in the CS, PHV, and NC groups. Additionally, the mother-child relationship expectations of PPP children became more positive over the course of the intervention as compared with children in the PHV and NC groups. These results suggest that a model of intervention informed by attachment theory (PPP) is more effective at improving representations of self and of caregivers than is a didactic model of intervention (PHV) directed at parenting skills. The results contradict predictions that would emanate from the meta-analysis of interventions targeting maternal sensitivity and child attachment (Bakermans-Kranenburg, van IJzendoorn, & Juffer, 2003). Because the intervention focused on changing representational models utilizing a narrative story stem measure, outcomes that might be expected to improve more dramatically in the PHV model (e.g., parenting skills, knowledge of child development) could not be addressed.

Because this intervention and the intervention for maltreated infants are the first to demonstrate that representations can be modified through the provision of an intervention informed by attachment-theory, it is important to consider factors that may have contributed to the efficacy of these approaches. We believe that the utilization of skilled and well-trained therapists, adherence to manualized treatment models, and monitoring of the fidelity of the provision of the interventions contributed to the efficacious findings. Moreover, given prior research that has found that the type of maternal attachment insecurity that is present may affect

to express criticism regarding their toddler-age children, and these youngsters exist in a relational context dominated by interspousal criticism, negative affect, and marital conflict (Cicchetti et al., 1998; Downey & Coyne, 1990; Rogosch, Cicchetti, & Toth, 2004). Radke-Yarrow, Belmont, Nottelmann, and Bottomly (1990) found that mothers with mood disorders were more likely to make negative attributions about their toddlers and the child's emotions, and there was correspondence between the negativity of attributions and statements about the self. Thus, insecure attachment and early negative self-development may portend the development of negative self-structure and self-understanding, self-cognitions and attributions, and self-schemata that constitute precursors to depressive disorder (Cicchetti & Schneider-Rosen, 1986; Cicchetti & Toth, 1995, 1998).

Intervention Design

To prevent the early development of a depressotypic developmental organization in young children of mothers with MDD, our strategy was to target the mother-child relationship to promote the development of secure mother-child attachment relationships and positive self-development. A number of interventions informed by attachment theory have been developed (Bakermans-Kranenburg et al., 2003; van Ijzendoorn, Juffer, & Duyvesteyn, 1995). However, the diversity in the multiproblem populations investigated, variation in the approaches taken, and multiple intervention components utilized (e.g., Egeland & Erickson, 1990; Erickson, Korfmacher, & Egeland, 1992; Lieberman, Weston, & Pawl, 1991; Lyons-Ruth, Connell, Grunebaum, & Botein, 1990) have made understanding the central processes contributing to effectiveness uncertain. Two interventions have been targeted specifically for altering attachment security in young children of depressed mothers (Cooper & Murray, 1997; Gelfand, Teti, Seiner, & Jameson, 1996). Although these studies demonstrated positive intervention effects, fostering the development of secure attachments was not accomplished. Further efforts in this area are thus needed.

When women have a depressive disorder, the focus of treatment, whether psychotherapeutic or pharmacologic, centers on the individual as an adult. Attention to the woman's role as mother and the implications for the depressive disorder on her children are not priority concerns. An implicit assumption is that if maternal depression abates, then any adverse effects on the child will be minimal. However, difficulties in the mother-child relationship may not easily dissipate, and the likelihood of future depressive episodes indicates that the child con-

tinues to be at risk. Thus, strengthening the mother-child relationship, promoting child competence, and averting the emergence of a depressotypic developmental organization are important considerations, in addition to the mother's depressive disorder.

The approach utilized herein was toddler-parent psychotherapy (TPP), an extension of infant-parent psychotherapy discussed earlier (Lieberman, 1992). Toddlerhood was targeted because of the central stage-salient task of the period, that is, the development of an autonomous self. Accordingly, we sought to foster increased security in the mother-child attachment relationship and thereby promote the positive development of self and corresponding positive internal representational models of self and other. Young children during the toddler period are growing in verbal skills and comprehension. As a result, the content of conversations between therapist and mother during the dyadic sessions of TPP and children's reactions must be given greater attention. Furthermore, as mothers and their toddlers increasingly are able to communicate verbally, both verbal as well as nonverbal communications offer opportunities for understanding the mother-child relationship. During this period, toddlers are increasingly asserting their autonomy, and attempts to negotiate differing maternal and child goals become more common during sessions. As the attachment relationship transforms, a goal-directed partnership between the mother and child represents an important achievement. As in IPP, TPP strives to expand maternal awareness and insight regarding influences on the mother's capacity to relate affectively and sensitively to the toddler and establish more positive maternal internal representational models of herself, her relationships, and her child.

Depressed mothers with a child approximately 18 months of age were recruited for a randomized preventive trial to evaluate the efficacy of TPP in improving the mother-child relationship and fostering competent development in the child, particularly secure attachment, with the intent of preventing a depressotypic developmental organization. Depressed mothers were recruited via referral from mental health professionals and through notices placed in newspapers, physicians' offices, and community libraries. To focus the RPT specifically on maternal depression rather than multiple co-occurring risk factors associated with poverty, the socioeconomic status of the participants was restricted to middle-class or higher. All depressed mothers met criteria for MDD with a major depressive episode occurring at some time since the child's birth; most mothers were currently depressed. In addition to the depressed mothers and their toddlers, a sample of

maternal responsivity to various intervention strategies (Bakermans-Kranenburg, Juffer, & van Ijzendoorn, 1998), it will be important to assess baseline attachment organization of mothers in relation to intervention outcome.

Preventive Intervention for Toddlers of Mothers with Major Depressive Disorder: Toddler-Parent Psychotherapy

Interest in the risk imposed on offspring by parental psychopathology was spearheaded by research on children of parents with Schizophrenia. Downey and Coyne (1990) noted that in this research, comparison groups were composed of children of parents with depression, with the anticipation that the difficulties would be substantially stronger in the children of parents with Schizophrenia. However, the findings indicated that the children of depressed parents exhibited the same range of disturbances. Relative to Schizophrenia, depressive disorders are far more prevalent. In the National Comorbidity Study, nearly 16% of the participants met lifetime diagnostic criteria for Major Depressive Disorder (MDD; Kessler, Davies, & Kender, 1997; Kessler, McGonagle, Zhao, & Nelson, 1994), and of those with a history of a depressive episode, 80% or more experience recurrent episodes. Consequently, offspring of depressed parents constitute a sizable population of children at high risk.

Mothers with MDD often struggle with the responsive care essential for infants and young children. Aspects of the disorder, including anhedonia, difficulty regulating negative affect, sleep disturbances, feelings of worthlessness, hopelessness, and helplessness, and difficulties in role functioning, are likely to challenge the early relational environment. Ensuing difficulties in parenting, sensitivity, responsivity, and affective attunement to the child may intrude on the development of the mother-child relationship, with adverse effects on child adaptation and functioning (Cicchetti, Rogosch, & Toth, 1998; Goodman & Gotlib, 2002). Moreover, for many of these mothers, depressive disorders have evolved with contributions from unresolved problems stemming from the mother's own attachment relationships in childhood (Arieti & Bemporad, 1978; Bowlby, 1980). Consequently, issues stemming from the mother's childhood attachment experiences may intrude on the quality of the attachment relationship formed with her own child via maternal internal representational models.

From the organizational perspective on development, precursors to later depressive disorders likely have origins in the quality of developmental competencies emerging

across the early years of life. In particular, difficulties in affect regulation, attachment, and self-development correspond to symptoms expressed in depressive disorders, including high levels of negative affect, interpersonal difficulties, and such diverse self-processes as low self-esteem, negative attributions, and feelings of helplessness and hopelessness. Evidence for atypicalities in biological systems of children of mothers with depressive disorders also have been documented. For example, infants of depressed mothers during the first 6 months of life have been found to have greater right-frontal brain activation as a result of lower left-frontal activation than comparison infants (Field, Fox, Pickens, & Nawrocki, 1995; Jones, Field, Fox, Lundy, & Davalos, 1997). This pattern of hemispheric asymmetry is associated with greater sensitivity and distraction to environmental change resulting in higher levels of distress. These early brain activation differences may suggest a diathesis for later depression and constitute a vulnerability that may be elaborated by subsequent parent-child relationship experiences. Other biological systems also are likely involved. For example, variation in the limbic-hypothalamic-pituitary-adrenal axis, which mediates the stress response, has been found in offspring of depressed mothers. In particular, 7-year-olds with high internalizing symptoms evinced high levels of baseline cortisol, and the best predictor of the elevated cortisol was maternal depression during the first 2 years (Ashman, Dawson, Panagiotides, Yamada, & Wilkinson, 2002).

A number of investigations of attachment in young children of depressed mothers have been conducted, and the results have been varied, based on differences in the demographic characteristics of the samples and variations in maternal depressive symptomatology and chronicity. Martins and Gaffan (2000) conducted a meta-analysis of studies in this area and concluded that there was evidence for increased rates of avoidant and disorganized attachment among these young offspring. The emergence of insecure attachment is a crucial concern because insecure attachment in infancy portends the development of insecure internal representational models of self and of self in relation to others. Evolving social, emotional, and cognitive competencies may be compromised and contribute to the development of a depressotypic developmental organization of psychological and biological systems (Cicchetti, Rogosch, & Toth, 1997; Cicchetti & Toth, 1998). Affect associated with the early development of the self has been shown to be more negative and less positive in toddlers of mothers with MDD, and insecure attachment in these offspring was related to affective instability and delayed self-emergence (Cicchetti et al., 1997). Depressed mothers are more likely

toddlers and their mothers ($n = 66$) who had no history of current or prior major psychopathology were recruited to serve as a normative comparison (NC) group. The children in the depressed and nondepressed samples were on average 20 months of age when baseline assessments were conducted; mothers averaged 31.6 years of age. Following baseline assessments, the depressed mothers and the toddlers ($n = 102$) were randomly assigned to the depressed intervention (DI) or the depressed control (DC) group.

The TPP was conducted with mothers from the time of completion of baseline assessments until children were 3 years old. Because of the middle-class socioeconomic status of the sample, sessions were conducted in an office setting rather than in the home, as with traditional IPP (Fraiberg et al., 1975). This was preferable to the middle-class mothers, who would have experienced sessions in the home as intrusive. Intervention sessions were typically scheduled on a weekly basis. The intervention lasted on average 57 weeks, and the mean number of sessions conducted was 45. Therapists received weekly group and individual supervision, and over the course of the implementation of the TPP intervention, fidelity was monitored by reviewing videotapes of the sessions.

Effects of Toddler-Parent Psychotherapy on Attachment

Prior to the intervention, substantial differences in Strange Situation attachment classification were found among the DI, DC, and NC groups. Consistent with expectations for greater insecurity in the depressed groups, significantly fewer children were classified as secure in the DI group (16.7%) and in the DC group (21.9%), as compared to the NC group (55.9%). Thus, approximately 80% of the toddlers of depressed mothers were found to have insecure attachment organizations. Although resistant and avoidant attachments were observed, the major differences in insecure attachment types between groups involved disorganized attachment. Whereas the rate of disorganized attachment in the NC group was relatively low (19.1%), significantly higher rates of disorganized attachment were found in the two depressed groups, 37.9% and 40.6% for the DI and DC groups, respectively.

At age 3, following completion of the TPP intervention, attachment organization was reassessed, and significant group differences in the distribution of attachment classifications were again observed. However, the pattern of group differences had changed markedly. Specifically, the rate of secure attachment had increased substantially in the DI group, to 67.4%, whereas no improvement in the rate of secure attachment was found in the DC group (16.7%). Moreover, the DI group no longer differed significantly from the

NC group (47.6%) in the rate of secure attachment, but the rate of secure attachment in the NC group far exceeded the rate in the DC group. The pattern of secure versus insecure classification at postintervention had shifted in accord with the predicted effects of the preventive intervention, with substantial increases in attachment security among children who had been in the preventive interventions; in contrast, insecure attachment characterized over 80% of the children of depressed mothers not receiving TPP.

The pattern of stability and change in attachment from pre- to postintervention indicated that change for insecure to secure was most commonly observed in the DI group (54.3%), whereas the most stable pattern in the DC group was stable insecure attachment (72.2%). Among children classified as avoidant at baseline, 63.2% of those in the DI group changed to secure at follow-up, contrasting with only 7.1% of the DC group. Dramatic change in disorganized attachment also was observed: 58.8% of children classified as disorganized in the DI group changed to secure, whereas only 8.0% of DC children who were disorganized changed to secure. Stable disorganized attachment was more common in the DC group (56.0%) than in the DI group (11.8%). Thus, the TPP preventive intervention was effective in promoting reorganization of different forms of insecure attachment into secure attachment, and in the absence of the intervention, youngsters of depressed mothers continued along a vulnerable trajectory of insecure attachment over time.

Effects of Toddler-Parent Psychotherapy on Cognitive Development

In addition to the important influence of TPP on promoting secure attachment organization, evidence for other intervention effects was examined. In particular, because of the goal of promoting self-development and autonomy and improvements in mother-child communication as a result of the intervention, the effects of TPP on cognitive development were investigated. At baseline, the Bayley Scales of Infant Development were administered, and the three study groups were found to be equivalent on the Mental Development Index. After the completion of the preventive intervention, all children at age 3 were administered the Wechsler Preschool and Primary Scale of Intelligence-Revised (WPPSI-R; Wechsler, 1989), and significant group differences emerged. The DI and NC groups continued to be equivalent in terms of Full-Scale IQ scores. However, the DC group attained lower mean scores than the DI and NC groups. Additionally, Verbal IQ scores, but not Performance IQ scores, showed the same pattern of group differences. Thus, in the absence of the preventive intervention,

children of depressed mothers did not appear to make the same cognitive advances as did children of nondepressed mothers. Moreover, the TPP preventive intervention appeared to safeguard the children of depressed mothers in the DI group, promoting competent cognitive development, consistent with that of the NC group.

Although the primary goals of TPP were to promote improved mother-child relationships and more competent child developmental attainments, it was anticipated that the strong therapeutic relationship and the corrective emotional experience afforded by TPP would contribute to reducing maternal depression. However, diagnostic and questionnaire assessments with the mothers following the intervention did not provide support for these changes. In fact, 30% of the mothers in the two depressed groups had major depressive episodes during the period from baseline to follow-up assessments. Consequently, whether subsequent depressive episodes influenced the intervention effects on cognitive development was examined for the DI and DC groups. Overall, whether mothers had a subsequent depressive episode did not influence child cognitive development. However, interaction effects of the DI group and subsequent depressive episode were found for Full-Scale IQ and Verbal IQ. For children in the DI group, cognitive scores were equivalent whether or not mothers had further depression. In contrast, for the DC group, children whose mothers had further depressive episodes attained lower cognitive scores than those whose mothers did not have a subsequent episode. These findings indicate that maternal depression poses ongoing risk to competent developmental attainments in children in the absence of intervention. Nevertheless, even though some mothers in the DI group continued to struggle with Major Depression, TPP appeared to protect these children's cognitive development.

Translation of the Preventive Intervention for Low-Income Mothers and Infants

Given the positive results of the RPT in demonstrating the efficacy of the preventive intervention for fostering positive developmental outcomes among toddlers of depressed mothers from a middle-class sample, a current RPT is under way to evaluate the efficacy of the intervention in a low-income sample. The difference in socioeconomic status and the high levels of social adversity faced by low-income families necessitated additional considerations in designing and implementing the intervention. Based on the implementation of IPP with the low-income maltreating sample, it was clear that attention to the poverty, limited resources, frequent single parentage, and dangerous neigh-

borhoods was crucial to reach this population. Accordingly, therapists experienced in working with low-income mothers implement the current preventive intervention. Because transportation difficulties, particularly with an infant, are frequent, the intervention is conducted in the home rather than being center-based. The home-based sessions reduce the demands on depressed women with young infants and instill trust between therapist and mother, as the therapist engages the mother in her home environment.

Another important reality faced by low-income women is the limitation in available and accessible mental health care. Accordingly, despite major depression, few low-income mothers are likely to seek or continue mental health treatment. Thus, an active intervention to treat maternal depression, interpersonal psychotherapy (IPT), was incorporated into the preventive intervention. IPT was chosen because its focus on interpersonal stresses and processes is consistent with relational issues addressed in IPP. Furthermore, because IPT is structured and time-limited, future implementation in the community is likely to be more feasible.

IPT also has been shown to be effective in treating maternal depression (O'Hara, Stuart, Gorman, & Wenzel, 2000; Stuart & O'Hara, 1995) and for treatment of depression in low-income populations (Spinelli, 1997). In the current RPT, depressed mothers and their infants are randomly assigned to one of three intervention groups: One group receives IPT, the second group receives IPT followed by 8 months of IPP, and the third group receives group informational meetings and referral to other mental health services in the community. A fourth demographically comparable group comprises mothers with no history of major psychiatric disorder and their infants. The evaluation study will determine whether IPP is effective in fostering positive child developmental outcomes in the low-income sample. Additionally, contrasting the IPT-only and the combined IPT/IPP intervention will address whether treating maternal depression alone is sufficient to alter child outcomes, or whether additional intervention focused on the mother-child relationship is crucial for promoting positive child developmental attainments.

FUTURE DIRECTIONS FOR PREVENTION TRIALS

Although much progress has been made in research on the prevention of mental health disorders, there are many important next steps that the field needs to address. In this section, we comment on the need for (1) continued refinement of the design and analysis of preventive intervention

trials, (2) greater attention to effectiveness and efficacy trials, and (3) a better understanding of the implications advances in behavior and molecular genetics has for prevention science.

Design and Analysis of Preventive Intervention Trials

Although an exhaustive review of the mental health preventive intervention literature was not an objective of this chapter, recent reviews suggest that randomized control trials with long-term follow-up are the exception rather than the rule. Equally rare are prevention trials where the putative mechanisms of intervention change are rigorously assessed and tested. Even rarer are trials where the costs of the intervention are enumerated and the ultimate value of the intervention determined based on a cost-benefit or cost-effectiveness analysis (see Haddix, Teutsch, Shaffer, & Dunet, 1996, for a comprehensive treatment of cost-benefit analysis in the context of preventive intervention trials). Thus, in terms of future directions, there is a clear need to remedy each of these shortcomings.

An equally important set of issues that must be addressed revolves around the analysis of the data from preventive and treatment intervention trials. In most randomized trials of preventive and treatment interventions, the estimation of intervention effects is complicated by variation in the degree to which an intervention is provided to and/or taken by the targeted population as designed. Barnard, Du, Hill, and Rubin (1998) use the term “broken randomized experiments” to refer to intervention trials where such variation in the receipt and/or provision of the intervention is present. Broken randomized experiments stem from the obvious fact that intervention researchers cannot ethically require the intervention recipients or providers to actually take or implement the intervention as designed. Rather, as Frangakis and Rubin (1999, 2002) point out, they can only randomize “encouragement” to participation. Accordingly, Frangakis and Rubin refer to randomized preventive and treatment and intervention trials as “encouragement studies,” where the focus is not only on the effect of encouragement itself (assignment to the intervention condition), but also on the effect of the intervention being encouraged.

A common practice among intervention researchers is to ignore in their evaluation of intervention effects the presence of variation in the degree to which an intervention is provided to and/or received by the targeted population as designed. This is typically referred to as an intent-to-treat analysis (ITT), where one simply estimates the difference in mean outcomes between those assigned to the interven-

tion group and those assigned to the control group. The ITT analysis thus yields the causal effect of intervention assignment and not the treatment received (Little & Yau, 1998). Although the ITT estimate of the effect of intervention assignment is protected from bias by randomized treatment allocation, it is distorted by the fact that variation in the receipt and/or provision of the intervention is ignored. As an alternative to the ITT analysis, intervention researchers often resort to an “as-treated analysis,” wherein only those who completed and/or provided the intervention as designed are considered in the comparison with the control group. As Little and Yau point out, the problem with this approach is that randomization is violated.

In recent years there has been substantial progress in the analysis of encouragement designs based on building bridges between statistical and econometric approaches to causal inference. In particular, the widely accepted approach in statistics to formulating causal questions is in terms of “potential outcomes.” Although this approach has roots dating back to Neyman and Rubin in the context of perfect randomized experiments (Neyman, 1923; Rubin, 1990), it is generally referred to as Rubin’s causal model (Holland, 1986) for work extending the framework to observational studies (Rubin, 1974, 1977) and including modes of inference other than randomization-based—in particular, Bayesian methods (Rubin, 1978, 1990). In economics, the technique of instrumental variables (Haavelmo, 1943; Tinbergen, 1930) has been a main tool of causal inference in the type of nonrandomized studies prevalent in that field. Angrist, Imbens, and Rubin (1996) showed how these approaches can be viewed as completely compatible, thereby clarifying and strengthening each approach. The result was an interpretation of the instrumental variables technology as a way to approach a randomized experiment that suffers from variation in the degree to which an intervention is provided to and/or taken by the targeted population as designed, such as a randomized encouragement design.

In encouragement designs with compliance as the only partially uncontrolled factor, and where there are full outcome data, Imbens and Rubin (1997) extended Rubin’s (1978) Bayesian approach to causal inference to handle simple randomized experiments with noncompliance. Imbens and Rubin focused on estimating the average intervention effect for compliers, which they termed the complier average causal effect (CACE). More specifically, CACE is the effect of the randomized encouragement on all subjects who would comply with their treatment assignment, no matter which assignment they would be given.

As an alternative to the Bayesian approach to CACE analysis, Jo and Muthén (2001, 2002) describe the use of

the random coefficient growth mixture modeling framework for estimating CACE in intervention trials featuring single and repeated assessments of intervention outcomes. Jo and Muthén (2002) also explore an approach for dealing with the complication that compliance is rarely measured in intervention trials such as ours on a binary scale (yes or no). Rather, it is typically measured on an ordinal, interval, or continuous scale. Jo (2002b) studied the estimation of intervention effects with noncompliance under alternative model specifications; Jo (2002a) focused on model misspecification sensitivity analysis in estimating causal effects of interventions with noncompliance. In another work (Jo, 2002c), the issues of statistical power and estimating it in randomized intervention trials with noncompliance were addressed.

Despite the considerable advances made in the analysis of randomized encouragement designs, a number of complications often encountered in trials where randomization occurs at the level of the group (schools, classrooms, clinics, etc.) rather than at the level of the individual remain to be dealt with if valid estimates of intervention effects are to be obtained in the presence of variation in the level of intervention implementation fidelity. First, besides the fact that compliance or fidelity is typically measured on an ordinal, interval, or continuous scale, methodologically rigorous intervention trials typically assess the compliance behaviors of those providing it as well as of the participants assigned to receive it. Moreover, multiple indices of the compliance behaviors of the recipients and providers are typically gathered. The second complication involves the modeling of treatment-baseline interactions. More specifically, from a developmental perspective, one assumes that children or adults do not proceed in lockstep fashion in terms of their social and behavioral development. This raises the question of whether the effects of an intervention designed to target social and behavioral development will vary as a function of the variation across the participants in their developmental course prior to the intervention (see, e.g., Shirk, 1999; Toth & Cicchetti, 1999). To study such a treatment-baseline interaction (or treatment-trajectory interaction), one must switch from a pretest-posttest analysis framework (essentially an ANCOVA-type analysis) to the growth mixture modeling framework as described in Muthén et al. (2002). A third complication centers on trials where randomization to intervention condition is done at the group level (e.g., children are clustered within classrooms and schools). Here, the data are multilevel, which must be taken into account in estimating intervention effects.

Another important methodological challenge that prevention researchers face is the fact that they often collect infor-

mation from multiple informants and/or via multiple methods. Yet up until now, there appeared to be little guidance in the literature as to methodologically and conceptually sound ways to integrate data from multiple informants and methods. Kraemer and colleagues (2003) offer a framework for accomplishing this task that makes sense from both a conceptual and a statistical standpoint. In their model:

The choice of informants is based on conceptualizing the contexts and perspectives that influence expression of the characteristic of interest and then identifying informants who represent those contexts and perspectives in such a way as to have the weaknesses of one informant canceled by the strengths of another. (p. 1566)

Kraemer and colleagues go on to elaborate a sequence of steps and procedures to integrate data from multiple informants:

1. A reliable and reasonably valid informant's report (I) comprises information on the trait or characteristic in question (T), some contribution from the context in which that informant is likely to observe the subject (C), a contribution from the perspective from which that informant views the subject (P), and random error (E). Each of these pieces of information, or sources of variance, can be defined as orthogonal latent variables.
2. For this three-dimensional model, we need at least three informants, each carefully selected to report reliable information about the specific characteristic, knowing that no one informant has all the pertinent information.
3. In selecting our informants, we would not choose informants likely to give collinear (highly correlated) reports because they would simply reproduce the same incomplete information.
4. Rather, we would try to select informants likely to give orthogonal (valid, but not redundant) reports, in such a way as to have the flaws (i.e., variability in the data that is not linked to the target characteristic) in one informant's data "corrected" by other informants.
5. Instead of asking, "How many informants do we need, and how do we combine their reports?" we suggest that the question should rather be, "How do we select informants in such a way that the imperfections in one informant's reports are corrected by another's reports?"
6. To reduce the influence of perspective (P) and context (C), one triangulates the data by using a mix-and-match strategy, in which specific selected contexts are viewed from the same perspective and selected perspectives are viewed in the same context. By choosing informants to implement this mix-and-match strategy, one structures the data from multiple informants in such a way that principal-component analysis will yield a gold standard measure as the first principal component, T^* , and measures of the

contrasts in context and perspectives as the second and third principal components (C^* and P^*).

7. If the theory and implementation are correct, T^* will be a reliable and valid measure of T . C^* and P^* are both reliable measures, but they are invalid for T . Thus, the model removes from T^* the sources of error about T that are represented by C and P in the individual informants' reports. (pp. 1575–1576)

These seven steps that Kraemer and colleagues (2003) elaborate provide an excellent roadmap for the design and analysis of future prevention trials. Adherence to these steps should serve to provide a more efficient and valid approach to assessing and reporting on the impact of preventive intervention trials when multiple informants and methods are employed.

These are some of the key design and analysis issues that will need to be addressed in future preventive intervention trials. This overview was not meant to be an exhaustive treatment of the topic. Shadish (2002) identifies a number of additional methodological and analysis issues that will need to be addressed in future preventive intervention field trials.

The Need for Effectiveness and Efficacy Trials

Although there is a continuing need for more randomized control trials of preventive interventions with long-term follow-up, recent research reviews and reports on efficacy studies document the growing number of preventive and other interventions that either reduce the onset of common mental and substance disorders or decrease the duration and disability of initial episodes of these disorders (Burns, Compton, Egger, Farmer, & Robertson, 2002; Burns, Hoagwood, & Mrazek, 1999; Catalano, Berglund, Ryan, Lonczak, & Hawkins, 1998; Coie et al., 1993; Greenberg, Domitrovich, & Bumbarger, 1999, 2001; Kazdin, 2000; National Institute of Mental Health, 1998; Olds, Robinson, Song, Little, & Hill, 1999). As described by Nathan, Stuart, and Dolan (2000, pp. 964–965):

Effectiveness research aims to determine whether treatments are feasible and have measurable beneficial effects across broad populations and in real-world settings, whereas the focus of the efficacy trial is on the performance of the intervention given the controls employed by the investigator.

Despite the growing number of efficacy studies demonstrating that common mental disorders can be prevented or their consequences greatly reduced when treated early, few

research studies examine (1) the extent that efficacious programs exhibit equally positive outcomes when implemented in natural service/treatment settings, (2) how dosage and quality of implementation affect outcomes, (3) how different program models and training strategies affect outcomes, and (4) the conditions necessary for successful program outcomes in natural settings with local ownership of the intervention process (Mrazek & Haggerty, 1994). These four issues constitute the key differences between efficacy and effectiveness research.

Earlier we discussed the prevention research cycle contained in the IOM report on the prevention of mental disorders (Mrazek & Haggerty, 1994). A critical juncture in the cycle centers on the progression from efficacy to effectiveness trials. We argue that the focus on feasibility in the prevention research cycle should not be restricted to the effectiveness stage. Rather, prevention scientists should consider in the efficacy stage the capacity of the existing public health structures and institutions to deploy their intervention if it is found to be efficacious. Here we are talking about not only the affordability of the intervention, but whether the relevant public health agencies have an efficient and effective means of gaining access to the population of interest. Preventive interventions based in public school settings have the advantage that by law children in the United States have to attend school from age 5 to age 16. But few social or public health institutions offer the access that the public schools do. Prevention scientists must also consider whether the public health institution that will likely be charged with the deployment of their preventive intervention has the personnel with the necessary expertise and motivation to implement it.

Along these lines, Schoenwald and Hoagwood (2001) integrated the findings from the operations research, industrial organizational psychology, community psychology, and educational sociology literatures. They then derived a conceptual model that identifies the key principles and relevant issues with respect to successful dissemination, adoption, implementation, and sustainability of innovation. These key principles are largely consistent with those elaborated by Rogers (1995) in his model of the diffusion of innovation and include (1) perceived relevance of the innovation to the system and extra organizational systems, (2) the credibility of the innovation to these systems, (3) the clarity of the innovation, (4) whether the innovations contrast sharply with prevailing practices, and (5) the extent to which the prevailing practices are supported by fiscal, organizational, and values structures.

In terms of conceptual models and empirical research specific to the influence of organizational context on the

delivery of children's mental health services, Glisson and colleagues (Glisson, 2002; Glisson & Hemmelgarn, 1998; Glisson & James, 2002) have done groundbreaking work. Their work has largely centered on the organizational context of community-based child welfare agencies and has focused on three key constructs: (1) organizational climate (i.e., the way persons perceive their work environment); (2) organizational culture (the ways things are routinely done in an organizational unit that are reflective of the norms and shared expectations of an organizational unit); and (3) organizational structure (the formal aspects of an organization, including elements such as the centralization of power and formalization of roles in an organization). Glisson and Hemmelgarn provided evidence of the impact of the organizational climate on psychosocial outcomes of children being seen in the child welfare system in Tennessee; Glisson and James report that service quality was associated with organizational culture.

McDougal, Clonan, and Martens (2000) offer a model involving the role of organizational change in the delivery of high-quality mental health services in schools that is likely applicable to most preventive intervention trials. Organizational readiness (e.g., support and active participation with administration and staff about the goals of the project), implementation support (support for training, supervision, and monitoring), and support for expansion of the model and its diffusion were identified as keys to successful implementation, diffusion, and maintenance.

In addition to McDougal et al. (2000), Hoagwood and Johnson (2003) and Ringeisen, Henderson, and Hoagwood (2003) identify organizational issues unique to school settings that may influence the delivery of evidence-based child mental health interventions. As with McDougal et al.'s model, many of the elements of their framework are relevant to preventive interventions in general. The issues they identify are largely consistent with those described by McDougal et al.: (1) whether the individuals chosen to implement the evidence-based interventions have roles associated with mental health and have played a role in either intervention development or implementation planning; (2) whether professional training and ongoing infrastructure are in place to support the providers in the implementation of the interventions; (3) whether current intervention programs and their allotted resources add to or detract from the implementation of the evidence-based mental health interventions; (4) whether such evidence-based interventions replace and improve on existing programs (maximizing available resources) or take valued resources from existing programs; (5) whether the school resources necessary to support an evidence-based intervention exist or have to be

created, supported, and sustained; and (6) whether the primary outcomes of the evidence-based interventions are seen as consistent or conflicting with a school's response to state and federal academic accountability concerns.

To summarize, there is a need for effectiveness as well as efficacy research in prevention. Although Nathan et al. (2000, p. 977) note that there is currently an "absence of agreement on the essential components of either efficacy or effectiveness trials," Kraemer (2000) has sought to reconcile these conflicting views. She suggests that efficacy and effectiveness be seen as representing the anchor points on a single continuum, as opposed to separate and distinct entities. Consistent with Kraemer, Hoagwood, Burns, and Weisz (2002) offer a phased, or incremental, approach to effectiveness research that is consistent with the prevention research cycle described in the IOM report (Mrazek & Haggerty, 1994). Hoagwood et al. contend that this incremental approach represents a "profitable conjunction" of science to service in mental health research.

Implications of Advances in Behavior and Molecular Genetics for Prevention

Developmental research has focused on understanding how the family and relationships within the family impact child and adolescent adjustment. In general, studies examining the impact of family relationships on adjustment have found that warm and supportive relationships within the family are associated with positive child and adolescent outcomes, whereas coercive and conflictual relationships are associated with the development of problems (e.g., Cummings, Goeke-Morey, & Dukewich, 2001; McCoby, 2002; Markman & Jones-Leonard, 1985; Patterson, Crosby, & Vuchinich, 1992). Because the majority of research in this area has not used genetically sensitive designs and in most cases has not examined more than one child per family, it has not been possible to distinguish environmental from genetic contributions to these associations. The need to consider genetic influences on family relationships is clear based on the rapidly accumulating number of studies that have found evidence for genetic influences on measures of family environment, ranging from parent-child relationships (e.g., Neiderhiser et al., 2004; Plomin, 1994; Towers, Spotts, & Neiderhiser, 2001) to sibling relationships (Bussell et al., 1999) to marital relationships (Spotts et al., 2004).

There has been a recent flurry of research examining genotype-environment interaction, many of these studies examining nonclinical samples of twins or siblings (e.g., Koeppen-Schomerus, Eley, Wolke, Gringas, & Plomin,

2000; Wichers et al., 2002). In addition, there are at least two studies that have found evidence for the interaction between a specific gene and a particular environment (Caspi et al., 2002, 2003). These findings of interactions between genes and the environment have inspired many researchers to take a second look at the importance of genes and genotype, especially in the context of a well-characterized environment. In part, this is because the field has long suspected that the interplay between genes and environment was interactional and not simply additive. In fact, some had proposed that disentangling the effects of genes from the effects of the environment was a nearly hopeless endeavor (Gottlieb, 1999). The recent findings of clear and significant interactions between genes and the environment indicate that this is not the case. The challenge remains, however, of how to translate such findings into prevention. Some have suggested that pharmacological intervention strategies may be appropriate (Caspi et al., 2002), although behavioral strategies focused on changing the environmental aspects of the interaction are also likely to be fruitful. In many cases, the information needed to target a pharmacological intervention will not be available, so somewhat broader behavioral interventions may be the only feasible approach, at least in the near future. One message that is clear from findings of genotype \times environment interaction and genotype-environment correlation is that targeted interventions are much more likely to be effective as they are more likely to incorporate a response to an individual's genotype.

Practical Implications and Limitations of Genetic Research for Informing Prevention

The most useful and immediate implication of findings from genetic research for prevention is in increasing our understanding of the etiology and processes involved. Through studies that have clarified genotype-environment correlation and interaction, it is clear that environmental factors do not operate independently of an individual and that at least part of the individual influence is through genetic factors. Both quantitative behavioral genetics and association-based molecular genetic designs are population-based and provide little information about *individual* risk. In other words, although knowing an individual's genotype may provide some information about the sorts of environments he or she may be particularly sensitive to—such as high levels of stress for those with the homozygous short form of the 5-HTTLPR polymorphism—the amount of total variance accounted for in predicting outcome is modest. Nonetheless, there are few studies of specific nongenetic risk factors that account for large portions of variance. In both cases, it is the accumula-

tion of risk factors or the interaction among different risk factors that provides the best description of risk.

Based on the current state of the fields of quantitative and molecular genetics, there are three primary messages for prevention:

1. Individual characteristics have an important and substantial impact on environment, often for genetic reasons, at least in part.
2. Because most genetic designs are population-based, changing the environment will result in a change in outcome. In other words, heritability does not imply immutability.
3. Genetic factors may be protective. Although it is common to emphasize interactions in terms of a specific risk gene or genotype interacting with a specific high-risk environment, the flip side is that individuals with a different genotype or gene are protected even in high-risk environments. This is news and is consistent with much of the literature on resilience. We already knew that a low-risk environment was associated with fewer problems, but understanding that genes and genetic factors can operate in a similar way is also important and underscores the role of a wide range of resiliency factors that may not be considered.

It also is important to consider the extent to which preventive interventions may alter gene expression. Among genetically vulnerable individuals, for example, offspring of parents with major mental disorders, environmental stress and adversity are likely involved in activating genes that are influential in the manifestation of different forms of psychopathology. Through preventive interventions, the individual may be instilled with increased capacities for coping with stress and improved physiological and neurobiological self-regulation. As a result, the expression of genes associated with psychopathology may be reduced. As sophistication in the understanding of genetic process in vulnerability to psychopathology increases, it will be important to examine how preventive interventions may operate in the moderation of the expression of genes contributing to mental disorders.

To summarize, advances in behavior and molecular genetics may ultimately allow for the tailoring of selective and indicated preventive interventions to reflect an individual's genetic makeup, which, in turn, should facilitate the appropriate matching of individuals to efficacious interventions. Besides leading to improved intervention outcomes, such matching should ensure that the finite mental health resources available from the standpoints of cost and the number of well-trained and qualified providers are more efficiently allocated. In addition, the individual receiving

the tailored intervention would be spared the discouragement and delay in symptom relief associated with a failed intervention experience. The fact that universal preventive interventions target the population as a whole likely precludes the matching of an intervention to an individual's genotype. Nevertheless, variation in response to the universal preventive intervention could serve to identify those who would benefit from genetic screening and the tailoring of an indicated or selective preventive intervention to their genetic makeup.

Despite the great promise of behavior and molecular genetics to inform the next generation of preventive interventions, a number of challenges must be met before that promise can be fully realized. We identify just a few of those challenges here. First, in terms of infrastructure, what agency, institution, or organization will be responsible for collecting, analyzing, storing, safeguarding, and reporting on and interpreting an individual's genetic information? Where will the funds come from to cover the costs of such genetic screening? Second, new interventions, or variants of existing ones, will need to be developed for those individuals whose genotype is associated with a failed or poor intervention response to the currently available interventions. This will require a more precise understanding of the mechanisms by which genes and existing interventions have their effect on an individual. Such knowledge would likely be necessary before existing interventions could be refined or new interventions developed to accommodate the nonresponders. The importance of having interventions available to address the needs of the various subgroups within the larger population is that individuals may be denied intervention resources owing to evidence that their genetic makeup was associated with a poor response to existing interventions. Third, given that intervention response is typically measured with error (e.g., participant self-reports, clinical observations), we will be faced with the same concerns raised by Kraemer et al. (1999); that is, the choice of a cut point cannot be based on statistics alone, but on what the social policy and clinical decision makers judge to be acceptable in terms of the consequences of emphasizing one form of misclassification versus the other.

Integrating Biological and Psychological Processes in Preventive Intervention Evaluations

The recent biological and genetic research has implications not only for informing prevention (i.e., determining targets for intervention, inclusion criteria) but also has significant implications for evaluation of preventive interventions. The conceptualization of most preventive interventions and the design of measurement batteries for preventive trial evalua-

tions are currently dominated by assessments of processes at the psychological and behavioral level. Prevention trials are evaluated for the degree to which they are successful in reducing behavioral symptoms and rates of clinical disorder and improving developmental competencies; measures of changes in psychological and environmental processes hypothesized to account for the intervention effects also are central. However, attention to neurobiological and physiological systems in prevention research has been limited. From the integrative perspective of developmental psychopathology, prevention scientists should strive to integrate biological assessments into the evaluation of preventive trials to derive a more comprehensive understanding of intervention effects. Accordingly, we advocate a multiple-levels-of-analysis approach (Cicchetti & Blender, 2004; Cicchetti & Dawson, 2002) in the design of prevention research.

The dearth of attention to biological processes in prevention evaluation may stem in part from beliefs that biological processes are not malleable or are less amenable to positive change as a result of experience. Evidence for neurobiological change in response to changes in the environment may be less apparent in normative populations where there is likely greater stability in supportive milieus. Although adversity and trauma are known to be detrimental to biological systems, how preventive interventions may contribute to recovery or repair of biological sequelae is little understood. A dynamics systems view posits bidirectional transactions between different levels of organismic organization, and in so doing it must be recognized that experience influences biology. While biological factors influence psychological processes, psychological experience also exerts action on the brain by feeding back on it to modify gene expression and brain function, structure, and organization (Cicchetti & Tucker, 1994; Eisenberg, 1995; Kandel, 1998). Thus, it is important to consider how changes in experience and behavioral functioning resulting from preventive interventions may alter biological processes.

The concept of neural plasticity offers a valuable heuristic for conceptualizing how preventive interventions may affect brain structure and function, contributing to resilience among individuals confronted with adversity (Curtis & Cicchetti, 2003). Analogous to recovery from physical injury to the brain, neural plasticity also may involve recovery from the damaging effects of trauma and extreme stress. Adverse environmental experience can induce physiological changes in the brain; conversely, experiences to ameliorate and safeguard against severe adversity may similarly produce physiological changes that are advantageous to the CNS (Cicchetti & Tucker, 1994; Nelson, 1999). Greenough and colleagues (Black, Jones, Nelson, & Gree-

nough, 1998; Greenough & Black, 1992; Greenough, Black, & Wallace, 1987) identify two forms of neural plasticity in mammalian brains: experience-expectant and experience-dependent plasticity. Most notably in early development, the brain “expects” to receive particular forms of information from the environment, and based on input, an early overabundance of neurons is pruned and new neuronal connections are formed as brain development proceeds. Appropriate timing and quality are important for optimal brain development, whereas deprivation and atypical experience may lead to detrimental consequences for brain neurobiological development (Cicchetti & Cannon, 1999). Given the rapid rate of growth and organization occurring during the early years of life, early interventions that alter adverse and stressful environments may influence the type of brain that emerges during this important period of neurobiological epigenesis. In contrast to experience-expectant plasticity, experience-dependent plasticity occurs in later periods of development as the established yet evolving brain responds to new experience through the formation of new neural connections. Thus, for high-risk individuals who are confronted with multiple environmental stresses, the positive effects of preventive interventions may occur in part through alterations that are set in motion in the structure and functioning of neurobiological systems.

In broad terms, many preventive interventions strive to reduce stress experienced by children exposed to social adversity and multiple risk factors. Accordingly, inclusion of physiological stress measurements in preventive trial measurement batteries would greatly augment knowledge regarding physiological responses to preventive interventions, in tandem with changes in psychological functioning. In recent years, research on rodents, nonhuman primates, and humans has focused on the effects of stress and social adversity on the neuroendocrine system (Gunnar, 1998; Ladd et al., 2000; Meaney, 2001; Sanchez, Ladd, & Plotzky, 2001; Sapolsky, 1992, 1996). The activation of the hypothalamic-pituitary-adrenal (HPA) axis in response to stress is an adaptive mechanism serving a protective function for the organism (McEwen, 1998). However, extreme and prolonged stress may dysregulate neuroendocrine functioning, resulting in damaging effects to neurons. Measuring the stress hormone cortisol through saliva sampling has provided an easily accessible window into neuroendocrine regulation in biobehavioral studies. In preventive intervention trials, measurement of average basal cortisol levels and cortisol reactivity in response to stress could readily be incorporated into pre- and postintervention and follow-up assessment batteries. In so doing, improvements in neuroendocrine functioning and concomitant relations to be-

havioral change could be articulated for a more complete appraisal of the range of impact of the prevention trial and processes through which its effects are achieved.

Investigations of emotion processing and emotion regulation constitute another area in which behavioral and neurobiological changes resulting from preventive interventions could be examined in tandem. Research on brain hemispheric asymmetry in electroencephalogram (EEG) activation indicates generally that positive emotions are processed by greater activation of the left hemisphere, whereas negative emotions are associated with greater right hemisphere activation (Davidson, Ekman, Saron, Senulis, & Friesen, 1990; Fox, 1991). Evidence exists that adults diagnosed with depression exhibit reduced left prefrontal cortex activation (Henriques & Davidson, 1991), and reduced left frontal EEG activation has been observed among infants and toddlers of mothers with depression (Dawson, Grofer Klinger, Panagiotides, Spieker, & Frey, 1992). Consequently, it would be interesting to incorporate longitudinal EEG measurements of hemispheric asymmetry as a component of, for example, preventive interventions designed to reduce the risk for depression. Altering patterns of hemispheric activation could accompany reduction in the risk for depressive symptomatology resulting from the intervention, and the dynamic interrelations between brain and behavioral systems would be clarified, particularly in terms of the multiple levels at which intervention effects may occur.

Other technologies utilized in investigations of brain structure and function also could be applied to understanding preventive intervention effects. For example, psychophysiological studies of neurological processing of discrete stimuli using EEG recordings of ERPs allow for monitoring of neural activity as it occurs. As previously discussed, ERP differences in response to anger stimuli have been observed in abused children (Pollak et al., 1997, 2001). As a preventive trial measurement, the extent to which there is a normalization of ERP waveform profiles as a result of intervention could be investigated. Similarly, atypicalities in the startle reflex have been observed in adults with Posttraumatic Stress Disorder (PTSD), including combat veterans and women who were sexually assaulted (Morgan, Grillon, Lubin, & Southwick, 1997; Orr, Lasko, Shalev, & Pitman, 1995), as well as children with PTSD (Ornitz & Pynoos, 1989) and maltreated children (Klorman, Cicchetti, Thatcher, & Ison, 2003). By including assessments of the startle reflex, preventive interventions designed to reduce the risk for anxiety disorders due to trauma could determine whether the effects of the intervention also occurred at the physiological level. Additionally, the inclusion of measures

of neuropsychological abilities and executive functions could identify improvements in, for example, attention, inhibition, memory, and logical planning resulting from a preventive intervention. The Cambridge Neuropsychological Testing Automated Battery (Sahakian & Owen, 1992) is a computer-administered neuropsychological assessment that could be readily included in an evaluation battery, thereby allowing for an examination of how potential change in executive functions was associated with reduced risk for the development of psychopathology.

Thus, the incorporation of a neurobiological framework into the conceptualization of preventive interventions holds considerable promise for expansion of knowledge regarding the complexity of the developmental process. By basing preventive trials on more comprehensive, integrative developmental theories of psychopathology, prevention research offers the opportunity to conduct developmental experiments that alter environment and experience in efforts to promote resilience among individuals faced with adversity. Determining the multiple levels at which change is engendered through preventive trials will provide more insights into the mechanisms of change, the extent to which neural plasticity may be promoted, and the interrelations between biological and psychological processes in risk, resilience, and psychopathology (Curtis & Cicchetti, 2003).

SUMMARY

In this chapter, we have elaborated a perspective on prevention that is informed by developmental psychopathology theory and complemented with theories and perspectives from epidemiology and public health. The prevention of mental and substance abuse disorders requires a solid understanding of the interplay among risk and protective factors and typical and atypical developmental processes. Results of preventive intervention programs will most certainly inform practice, but this chapter supports the position that it is also vital for prevention scientists to design prevention trials in such as way (i.e., randomized prevention trials) that allows the results to increase our understanding of development as well. Furthermore, following the carefully planned steps in the research cycle discussed, prevention programs with the most empirical support can be implemented in community or real-world settings to reach the broadest number of people and prevent, or alleviate, suffering from mental and substance abuse disorders.

Examples provided from the Johns Hopkins Prevention Intervention Research Center and the Mt. Hope Family

Center, University of Rochester, illustrated the cyclical information-sharing process between theory and practice. These exemplars also highlight the successful partnership between academia and community organizations required to effectively implement and research large-scale preventive interventions. We end the chapter discussing future research efforts. We believe a rich area of future prevention research is in the transactional relationship between biology and the development of mental health disorders.

As much as was written in this chapter about prevention research, the field of prevention is broader still, even that part focused on mental and substance abuse disorders. There are many established and promising programs of research that could not be covered in the confines of this chapter. Prevention also ranges across the life span, and programs for older adults, such as prevention of dementia in older age, are extremely valuable lines of research and practice.

Subject Index

- AAI. *See* Adult Attachment Interview (AAI)
- Abuse. *See* Maltreatment/abuse; Substance use/abuse
- Academic achievement, 191
- Acculturation, 615–616
- Acetylcholine, 83–84
- Achenbach Child Behavior Checklist. *See* Child Behavior Checklist (CBCL)
- Achenbach System of Empirically Based Assessment (ASEBA), 56, 57
- ACQ Behavior Checklist, 158
- Acquisition versus maintenance, 534
- Activational effects, gender and psychopathology, 81–82
- Actual/ideal self-attributes, very young children's inability to distinguish, 378
- Adaptation, school reform and indicators of, 496–497
- Adaptive Behavior Composite, 203
- Adaptive value, cultural practices, 589–590
- ADHD. *See* Attention-deficit/hyperactivity disorder (ADHD)
- ADHD Rating Scale IV, 169
- Adolescence. *See also* Childhood/adolescence:
 - attachment and psychopathology, 349–350
 - autonomy, 819–820
 - culture, 593
 - dark side of self-esteem in, 397–398
 - depression, 112–113
 - eating-disordered behavior, 398–399
 - ego development, 756–757, 777–778, 783–784
 - epidemiology, measuring psychopathology, 56
 - self-processes:
 - early adolescence, 390–399
 - late adolescence, 406–412
 - middle adolescence, 399–406
- Adult(s):
 - ego development, 759–761
 - incest offenders, 759
 - social functioning, and childhood/adolescent adversity, 731
- Adult Attachment Interview (AAI), 339, 341, 349, 352, 361, 362
- Affect Balance Scales, 780–781
- Age:
 - family, 570–571
 - at first exposure to risk factor, 59
 - stage dysynchrony, 759
- Agency, autonomy as, 802–803
- Agentive self, 728–731
- Aggression:
 - children, and dynamic systems, 890
 - isolation rearing and, 683
 - peers, 426–427, 468
 - role of physical aggression in conduct problems, 98
 - sex differences, 89–90
- Agoraphobia, 108. *See also* Anxiety disorders
- AIDS, epidemiology, 42, 68
- Ainsworth's Strange Situation, 340, 341
- Alcohol use/abuse. *See also* Substance use/abuse:
 - autonomy, 835
 - culture, 163–164
 - ego development and, 774–778
- AMBIANCE (Atypical Maternal Behavior Instrument for Assessment and Classification), 352
- Ambivalence, 941
- American identity, 658
- Amotivation, 799
- Amygdala, 250–252, 260
- Anhedonia, 941
- Anorexia nervosa. *See* Eating disorders
- Anterior cingulate cortex (ACC), 259
- Antisocial personality/Antisocial Personality Disorder (ASPD):
 - autonomy, 834–836
 - DSM nosology, 148
 - ego development, 759–760
 - emotional regulation, 834–836
 - general growth mixture modeling (GGMM) analysis, 989–991
 - psychoanalytic writings on, 708
 - as psychopathology of failed internalization, 834
 - testing taxonic conjectures, 945
 - trajectories, clusters of (dynamic systems methods), 924
- Antitypes, 228–229
- Anxiety disorders:
 - culture, 598, 602–606
 - ego development and, 768–771
 - origin and development, males/females, 108–111
 - agoraphobia, 108
 - generalized anxiety, 108
 - links between anxiety and depression, a developmental perspective, 111–112
 - panic disorder, 108
 - PTSD, 108
 - social phobia, 108
 - specific phobia, 108
 - psychoanalytic perspective and, 704, 709
 - developmental aspect (Anna Freud), 709
 - Freud's structural model, central role of, 704
- Anxiety Disorders Interview Schedule (ADIS), 57
- Anxiety Disorders Interview Schedule for DSM-IV-Child Version (ADIS-IV-C), 450–451
- Ascertainment bias in case identification, 46–47

- Asperger's Disorder, 450, 956
- Assessment, 139–175
 advancing, 164–166
 challenges to be met, 165–166
 diagnoses made from structured interviews showing mediocre agreement with clinical diagnoses, 165
 great variations in prevalence rates of *DSM* diagnoses made from structured interviews in epidemiological surveys, 165
 high rates of comorbidity, 165
 low to moderate cross-informant agreement, 165
 overview table, 166
 quantitative aids to meeting the challenges, 166–168
 revealed by studies of structured diagnostic interviews, 165–166
 test-retest attenuation, 165
- developmental psychopathology, 141–149
 developmental differences, 145–146
 epidemiological aspects, 147–148
 multivariate aspects, 148
 operational definitions, 148–149
 sources of data, 146–147
- diagnosis, 151–153
 comorbidity issues, 152–153
 diagnostic formulations, 152, 164
 diagnostic processes, 151, 164
 formal diagnoses, 151, 164
 quantification of categories, 168–172
- future directions, 172–175
 life span directions, 172–173
 multicultural directions, 173–174
 quantification of diagnostic criteria, 174
 use of multisource data, 174–175
 use of norms to evaluate interventions, 174
- life span perspectives, 140, 162
- longitudinal designs, 153–162
 accelerated longitudinal designs, 154–158
 growth curve designs, 159–162
 path designs, 157–159
- multicultural perspectives, 140–141, 162–164
- role in developmental study of psychopathology, 149
- taxonomy and, 149–151
- Assimilation, straight-line model of, 658
- Attachment, 333–364
 autonomy and; across life span, 817–822
 continuum of contextual risk, 354–356
 continuum of individual risk, 341–351
 adolescent and adult attachment, 349–350
 infant attachment, 342–348
 personality risk, 350–351
 preschool attachment, 348–349
 school-age attachment, 349
 continuum of relational risk, 351–354
 developmental pathways and, 337
 disruptions, 353–354
 family systems, 562, 786–787
 future directions, 361–364
 insecure or violent adult attachment relationships, 355
 intervention based on, 364
 levels of analysis, and intervention based on, 364
 loss of attachment figures, 353–354
 as mediating variable between adolescent and family variables, 786–787
 modeling transactional processes in developmental pathways leading to psychopathology, 356–360
 organization:
 as aspect of personality, 336–337
 measuring, 361–362
 as source of continuity, 337–339
 personality and, 336–337, 350–351, 785
 prevention intervention design, and theory of, 1000
 psychoanalytic perspectives, 729
 psychopathology and, 343–347
 risk factors, 343
 as stress regulatory system, 335–340
 trauma related to, 352–354
- Attachment Q-Sort, 341
- Attention, defined, 188. *See also* Joint attention
- Attentional control systems, 729, 731
- Attention-deficit/hyperactivity disorder (ADHD):
 causal pathways, 932
 culture, 598
DSM nosology, 148
 emotion knowledge, 271
 emotion regulation, 271–272
 environmental explanations, 96
 equifinal pathways, 933
 functional adjustment, 186
 functional deficits in right-sided PFA-striatal circuitry, 253
 gender and psychopathology, 95–96
 genetic/biological explanations, 96
 identifying children at risk, 954, 955
 joint attention, 296
 parenting and, 561–562
 risk/exposure, and meaning of time, 60
 selection of cognitive tests, 203
 smoking and, 683–695
 behavioral influences, 685–686
 behavioral and neural coactions, 689
 environmental and behavioral coactions, 688–689
 environmental influences, 684–685
 future directions, 690–694
 genetic influences, 687–688
 genetic markers as moderators of previous predictions, 693
 inattentive versus hyperactive-impulsive symptoms, 691–692
 multiple levels of influence, 684–688
 neural and genetic coactions, 689–690
 neural influences, 686–687
 prevention, 693–694
 psychostimulant treatment and, 692–693
 resilience, 694–695
 self-influences, 688
 self-reports, and onset of regular smoking, 691
 subtypes, 690–691, 955
- Attractors, 892–893, 896, 899
- Attribution theory, 800
- Authenticity, autonomy as, 801–802
- Authoritarian parenting, 815

- Autism:
 - developmental differences, 272–273
 - emotion and, 272–279
 - cognition connections, 273–274
 - expression, 274
 - knowledge, 274–276
 - empathy, 276–277
 - extreme male brain theory of, 94
 - future directions, 281
 - genetic/biological explanations, 93–94
 - growth trajectories, 234, 235
 - joint attention, 301–303
 - neurobiological processes in emotion regulation, 277–278
- Autism Diagnostic Interview (ADI/ADI-R), 303, 304, 450
- Autism Diagnostic Observational Schedule (ADOS), 201, 303, 304
- Autonomy, 795–841
 - attachment, intimacy, and relatedness across the life span, 817–822
 - adolescence, 819–820
 - childhood, 818–819
 - infancy, 817–818
 - old age, 822
 - young adulthood, 820–822
 - defining what it is, 796–804
 - agency, 802–803
 - authenticity, 801–802
 - internal perceived locus of causality, 797–800
 - true self, 800–801
 - will, 802
 - defining what it is not, 803–808
 - denial of implicit motives, 804
 - detachment or separation, 806–807
 - entailing of disembodied self, 804–805
 - independence from environments, 803–804
 - independence from others, 805–806
 - just a stage, 807–808
 - emotional integration, 825
 - emotional regulation, 822–828
 - caregiving in early development, 826
 - developing, 824–825
 - externalizing disorders, 834–837
 - borderline disorders, 836–837
 - conduct disorders and antisocial personality, 834–836
 - dissociative identity disorders (DID) and the fragmentation of self, 836
 - failures of internalization, 834–837
 - future directions, 838–841
 - holding environments, 826–828
 - impairments of, 828
 - internalization, 812–817
 - introjection, 812–813
 - social context, 814–817
 - internalizing disorders and, 829–834
 - introjection and self-disparagement, 832–834
 - obsessive-compulsive disorders, 830–831
 - obsessive compulsive personality (OCP), 830
 - paranoid personality, 831
 - rigid character, 829–830
 - intrinsic motivation, 808–811
 - field studies, 811
 - social context and, 809–811
 - self-determination theory (SDT), 837–838
 - support, 808–822, 826–828
 - defined, 811
- Autonomy stage (White racial identity), 637
- Behavioral Activation System (BAS), 260–263
- Behavioral disorders, “natural kinds,” 150
- Behavioral expressions, culture and, 594–595
- Behavioral influences on gene activity, 676
- Behavioral Inhibition System (BIS), 260–263
- Behavioral reactivity, early identification, 954
- Behavioral syndromes, and latent vulnerabilities, 945–946
- Behavior Assessment System for Children (BASC), 304
- Behavior and self-esteem in children, 375–376
- Bellak Ego Functions Interview, 775
- Berkson’s bias, 152–153
- Bimodality, 938–939
- Biological/environmental contributions, oppositional defiant disorder (ODD), 100–101
- Biological/family processes, 548
- Biological/genetic explanations:
 - eating disorders, 114
 - mood disorders, 104–105
 - substance abuse, 102–103
- Biological level of analysis, 540–541
 - external, 541
 - interaction between physical environment and biological factors, 541
 - internal, 540–541
- Biological/physical development, 87–88
- Biological sex differences, 79–87
 - brain structure and function, 84–86
 - genetic contributions, 79–80
 - neuroendocrine contributions, 80–83
 - activational effects, 81–82
 - organizational-activational hypothesis, 80–83
 - organizational effects, 81
 - neurotransmitter levels and activity, 83–84
 - acetylcholine, 83–84
 - dopamine, 84, 687
 - GABA, 83
 - sex steroids, 83
